To compare the above findings with the results obtained when the test was read after eighteen hours, an arbitrary titre of 1/32 or more at this time was taken as indicating a positive result It was then possible to show that the number of cases of rheumatoid arthritis giving a positive result after eighteen hours was 159 (55.6%) as compared with 140 (49%) with the one hour reading But the number of false positive cases was increased from 12 (1.9%) to 27 (4.4%) Since a gain in specificity is relatively more important for diagnostic purposes than is a small increase in sensitivity, reading the test after an hour was considered the method of choice Moreover the reading of the results is greatly facilitated by the one hour method which does not involve the estimation of an end point of agglutination, this criticism is applicable to the technique devised by Heller et al (1949), in which a positive result depended on agglutination in a titre of 1/28 or higher with complete agglutination in dilutions of 1/7 and 1/14

It was observed in serial tests that, when occasionally a positive case of rheumatoid arthritis became negative, it passed through a phase in which a negative result was obtained after an hour but agglutination in a titre of 1/32 or more was present after eighteen hours Hence the observation of a delayed reaction of this type is useful in that it indicates the necessity of repeating the

TABLE VI—CLINICAL SUBDIVISION OF 134 CASES OF NON ARTHRITIC DISEASE

Disease	No
Cardiovascular disease	33
Bacterial infections	19
Diseases of the nervous system	19
Tumours (mostly malignant)	13
Endocrine disorders	12

test It should then be emphasised that, though it is necessary and convenient to base positivity on the results of the test as read after an hour, additional information can be obtained by reading again after eighteen hours, and this should therefore be included as part of the technique

DISCUSSION

The factor in human sera which agglutinates sensitised sheep erythrocytes and is distinct from heterophil antibody is of considerable serological interest It seems to be present in relatively small amounts in the sera of some apparently healthy persons as well as in various diseases, but in some cases of rheumatoid arthritis its concentration is greatly increased, with the result that agglutination of sensitised cells may be evident when the serum is diluted a thousand times or more Since this work was completed, the papers of Jawetz and Hook (1949) and Heller et al (1949) have come to hand In examining the sera of 160 patients Jawetz and Hook followed in detail the technique devised by Rose et al (1948), and in a discussion of the test they mentioned that sensitised sheep cells were agglutinated

by some human sera even after exposure of the sera to ox cells or guinea-pig kidney, both of which absorb heterophil antibody Heller et al. showed that, with some human sera, preliminary absorption with normal sheep erythrocytes did not affect the power to agglutinate sensitised sheep cells Including my own, there are thus three independent demonstrations that the serum factor for sensitised sheep cells is not identical with heterophil antibody

This serum factor may be of importance in the study of agglutination phenomena, and it may possibly be related to the disease process of rheumatoid arthritis At present, however, its precise nature is unknown Believing it to be an antibody, Heller et al used the term haemagglutinin, but no substantial evidence identifying it as such has yet appeared Indeed, in preliminary experiments I have found that repeated absorption of a positive serum with sensitised sheep cells leads to a delayed reaction with only slight loss of agglutinating activity—a finding which would not be expected of an antibody

The results of the clinical trial strongly suggest that the test offers the advantage of considerable specificity, 91.5% of the positive results having been clinically diagnosed as rheumatoid arthritis Further, 5 of the 13 false positive results occurred in patients with arthritic disease which might easily have been labelled rheumatoid arthritis The results published by Heller et al on 157 cases generally agree with my findings A much larger arthritic and non arthritic control group will have to be studied before the test can be finally assessed

The high incidence of negative results in ankylosing spondylitis (97.6%) and osteo arthritis (98.1%) contrasts strikingly with the findings in rheumatoid arthritis The significance of the negative results in many cases considered to be rheumatoid arthritis on clinical grounds is not clear It has been suggested that the test is seriously limited as a diagnostic aid because positive results are obtained only in highly active cases of rheumatoid arthritis, or only when the characteristic X ray changes are present (Heller et al 1949) Although a detailed clinical follow-up of the positive and negative cases of rheumatoid arthritis has not yet been made, I have occasionally observed positive results in apparently classical cases of rheumatoid arthritis at a stage when X rays showed no definite abnormality Again, not a few cases of rheumatoid arthritis with a clinical history of six months or less have also been positive On the other hand, it is generally agreed that rheumatoid arthritis is an ill defined clinical syndrome which merges with various arthritic, peripheral vascular, and other diseases, and any test which facilitated the delineation of a single clinical group might be of value in the study of rheumatic disease.

SUMMARY

The test for rheumatoid arthritis devised by Rose et al has been critically examined, and it has been shown that the agglutination of sensitised sheep cells by some human sera is due to a factor distinct from heterophil antibody

From a consideration of this and other factors involved in the reaction a new technique has been developed

Of the 895 cases tested by this technique 153 gave a positive result, and of these 140 (91.5%) were diagnosed clinically as rheumatoid arthritis, this disease comprising 32% of the total number of cases

In 97.6% of 85 cases of ankylosing spondylitis, 98.1% of 107 cases of osteo arthritis, 94.2% of 120 cases of other forms of arthritis, and in 100% of 134 cases of non arthritic disease the test gave a negative result

My thanks are due to Prof S L Baker and Dr J H Kellgren for their constant interest and advice

various dilutions of hæmolysin is added to a series of tubes, each containing 0.25 ml of a 2% suspension of normal sheep cells. The mixture is allowed to stand for an hour to ensure sensitisation of the sheep cells, and then to each tube are added 0.25 ml of 0.85% saline solution and 0.25 ml of a 1/10 dilution of complement. The tubes are next placed in a water bath at 37°C for an hour. The highest dilution showing complete hæmolysis represents one hæmolytic dose. The titre of hæmolysin has varied from 1/600 to 1/4000. The agglutinin titre of the hæmolysin is determined at the same time as follows: 0.25 ml of various dilutions of hæmolysin is placed in a series of tubes, each containing 0.25 ml of a 2% suspension of sheep cells and 0.5 ml of saline solution. The tubes used for this estimation have the same internal diameter as those used for the test proper. After incubation at 37°C for an hour the titre is read with the naked eye and corresponds to the highest dilution showing agglutination. The agglutinin titre of hæmolysin used has never exceeded 1/100. To ensure that a given hæmolysin is suitable, it is used in a preliminary test of a standard human serum of known agglutinin titre for sensitised cells.

A 1% suspension of sensitised sheep cells is prepared by thoroughly mixing a volume of hæmolysin, containing one minimum hæmolytic dose, with an equal volume of a 2% suspension of normal sheep cells. The resulting suspension is allowed to stand for an hour at room temperature before being used in the test.

A 1% suspension of normal sheep cells is prepared from the same 2% suspension used for the preparation of the sensitised cells.

The test serum (derived from clotted blood) is inactivated at 57–58°C for 20 min. It is stable at least for some months when preserved frozen and for ordinary purposes may be stored at 4°C. A little over 1 ml of the serum is added to a centrifuge tube containing 0.5–0.75 ml of packed normal sheep cells. The tube is shaken, and the mixture is incubated in a water bath at 37°C for an hour. The cells are then spun down, and the serum is removed. This absorbed serum is now ready for the test proper.

The Test

Two rows of tubes (internal diameter 0.8 cm) are set up in a Kahn rack. The back row consists of twelve tubes, the front row of four. Doubling dilutions of the absorbed serum in 0.5 ml volumes are made so that the back row of tubes contains serum dilutions ranging from 1/2 to 1/4096 and the front row contains dilutions ranging from 1/2 to 1/16. Two additional tubes, each containing 0.5 ml of saline solution instead of serum dilution, are placed in the rack. 0.5 ml of the 1% suspension of sensitised sheep cells is added to each of the twelve tubes in the back row and to one of the two tubes containing saline solution instead of serum (sensitised cell control). 0.5 ml of the 1% suspension of normal sheep cells is added to each of the four tubes in the front row and to the remaining tube containing saline instead of serum dilution (normal cell control). The final dilutions of the serum under test thus range from 1/4 to 1/8192.

After each tube has been shaken the rack is placed in a water bath at 37°C for an hour. It is then removed, and each tube is gently inverted three times to resuspend the cells. The results are then read with the naked eye. The sensitised cell control, the normal cell control, and the four tubes containing normal cells should show no trace of agglutination. Agglutination of sensitised cells in a dilution of 1/4 (first tube) or higher constitutes a positive result. A serum whose titre for sensitised cells is known is included in each batch of cases.

RESULTS

Since April, 1949, this technique has been used in a clinical trial involving over 1000 cases. The sera were examined in weekly batches of up to 46 and so arranged that it was impossible for the person reading the results to know the origin of the serum under test. As previously mentioned, each test was also read after eighteen hours at 4°C, but, for reasons discussed below, the findings in the clinical trial were based only on the results obtained when the test was read after an hour at 37°C, as described above. Clinical material was obtained largely from three sources.

1. Every new patient attending the outpatient department of the Manchester Rheumatism Centre was tested.

TABLE IV—ANALYSIS OF RESULTS IN 895 CASES OF ARTHRITIS AND NON ARTHRITIC DISEASE

Group	Disease	Total	Positive	Negative
			No	No
1	Rheumatoid arthritis	286	140 (49.0%)	146 (51.0%)
2	Ankylosing spondylitis	85	2 (2.4%)	83 (97.6%)
3	Osteo-arthritis	107	2 (1.9%)	105 (98.1%)
4	Other arthritides (table v)	120	7 (5.8%)	113 (94.2%)
5	Indeterminate painful states	79	1 (1.3%)	78 (98.7%)
6	Rheumatic fever and acute and subacute rheumatism	17	0	17 (100.0%)
7	Non arthritic diseases (table vi)	134	0	134 (100.0%)
8	Miscellaneous sera—clinical diagnosis untraced	67	1 (1.5%)	66 (98.5%)

2. Samples of sera sent for the Wassermann reaction provided the bulk of the non arthritic controls.

3. A relatively few sera were obtained from selected inpatients of the Manchester Royal Infirmary.

A preliminary analysis of the results in 895 cases has been made. Of the total number 153 gave a positive reaction. Cases diagnosed clinically as rheumatoid arthritis comprised 32% of the total and 91.5% of the positive reactions. The 895 cases have been further divided into eight clinical groups (table iv).

Group 1 consisted of 286 cases diagnosed clinically as rheumatoid arthritis. Of these, 140 (49%) were positive and 146 (51%) negative. The group as a whole undoubtedly contained cases in which the disease had been inactive for years. On the other hand, there were early cases with a history of six months or less, some of which were positive. A detailed clinical analysis of the negative and positive cases of rheumatoid arthritis has not yet been made. A few of both negative and positive cases were repeatedly tested over periods of up to six months. With a few exceptions the positive cases remained positive and the negative cases remained negative.

Group 2 consisted of 85 cases of ankylosing spondylitis, 83 (97.6%) were negative and 2 (3.4%) were positive.

Group 3 consisted of 107 cases of osteo arthritis, 105 (98.3%) were negative and 2 (1.7%) were positive.

Group 4 consisted of 120 arthritic cases other than rheumatoid arthritis and ankylosing spondylitis (table v), 113 (94.2%) were negative and 7 (5.8%) positive. Although the number of cases in individual subgroups is too small for any final conclusions, it is worth noting that the results in disseminated lupus erythematosus contrast strongly with the rest.

Group 5 consisted of 79 patients who had attended the rheumatism clinic and been diagnosed as suffering from indeterminate painful states, to which labels such as fibrositis, neuritis, and psychogenic rheumatism are usually attached. All but 1 gave a negative reaction.

Group 6 consisted of 9 cases of acute rheumatic fever at various stages and 8 cases diagnosed as acute or subacute

TABLE V—ANALYSIS OF 120 CASES OF ARTHRITIC DISEASE

Disease	Total	Positive	Negative
Arthritis type undetermined	32	1	31
Lesion of intervertebral disc	25	1	24

Reviews of Books

Techniques in British Surgery

Editor RODNEY MAINGOT, F.R.C.S. London W B Saunders 1950 Pp 733 75s

Mr Maingot has collected together accounts of new—or in some cases specially difficult—operations by acknowledged authorities, of whom there are 28 besides himself. Every one of them is an expert, and the subjects dealt with are often of that troublesome kind, such as stress incontinence in the female, in which the experience of the general surgeon is not usually great. New operations which may be regarded as still on trial, such as thymectomy, and operations which are not uniformly successful, such as repair of hernia, are also included. The choice of subjects is catholic, and the presentation masterly. We know of no better description of Heller's operation for cardiospasm than that contributed by Maingot himself, and a high standard is throughout attained. The illustrations are very fine and the book will be used widely for reference. We hope the editor will fulfil his promise to add several sections in the future.

The Biochemistry of the Nucleic Acids

J N DAVIDSON, M.D., D.Sc., Gardiner professor of physiological chemistry, University of Glasgow London Methuen. 1950 Pp 163 7s 6d

THE use of the word "elementary" can be overdone, and this small monograph on the nucleic acids is not so elementary as the author suggests in his preface. It deals, in fact, with some of the most complicated problems in modern biochemistry, but it is written in such clear and simple language that it is a pleasure for even the non-specialised to read it.

From sound structural organic chemistry Professor Davidson gradually builds up the formulae of the nucleotides and nucleosides. Then he deals with the nucleases and ultraviolet absorption of the purine and pyrimidine rings. The application of this curious physical fact to the study of nucleic acid metabolism is a good example of modern technical application and achievement. An account follows of the chemical methods of estimating the two nucleic acids found in cells, and their distribution between the nucleus and the cytoplasm, for it is certain now that ribose nucleic acid (RNA) to modern biochemists, and plant nucleic acid to their predecessors) is abundantly present in the cytoplasm of mammalian cells, especially in those which are actively synthesising protein. The remainder of the book is devoted to the metabolism, synthesis, and biological function of the nucleic acids.

The whole book is up to date, and these last chapters even contain an account of most of the recent work with isotopes and labelled elements. The final chapter on the bacterial and viral nucleoproteins is one of the most stimulating of all. There are four pages of photographs, plenty of diagrams and graphs and ample references. It is cheering to see the truly international character of the research work on this subject.

Freud or Jung

EDWARD GLOVER, M.D. Glasg London Allen & Unwin. 1950 Pp 207 15s

Dr Glover, who is perhaps our most militant Freudian, subjects Jung's writings to merciless and mordant criticism. He points out that there are three ways in which attempts may be made to negate Freud's theory of unconscious mental functioning: first, to operate in terms of conscious psychology; secondly (the ways of Rank, Klein, and Adler) to exaggerate postnatal and constitutional influences; and thirdly, to abandon psychology altogether. Dr Glover surmises that Jung is nothing more nor less than a pre-Freudian who, having let himself be carried in the stream of Freudian thought, has ever since struggled to make his peace with conscious psychology. Even Jung's character-types, which have received wide recognition, are gleefully knocked down by Dr Glover: such descriptive labels as "introversion and extraversion" give no hint, he finds, of the complex dynamic and structural developments that lead to the formation of character. He demolishes Jungian psychology so easily that one wonders if his

main adversary is not another—the fellow-traveller or eclectic psychiatrist, whom he scolds for his shameful concern with therapeutic results and his neglect of creed and principles. The eclectic, he insists, must either accept the fundamental Freudian concepts of the unconscious mind or else cling to pre-Freudian views based on the conviction that mind and consciousness are synonymous. But when he claims that anyone who accepts the unconscious mind, infantile sexuality, repression, conflict, and transference, is accepting all psycho-analytical teaching, Dr Glover goes too far. Many who accept these phenomena are unable to digest a theory that recognises psychogenic causes only, and minimises the effects of organic and constitutional factors.

This zestfully written book with its robust and reasoned arguments strikes a blow at *Analytical Psychology* that might well be mortal, were it not that Jung is still very much alive and likely to make his answer.

Hystero-graphy in Cancer of the Corpus of the Uterus

OLAF NORMAN, from the röntgen diagnostic department, University Clinics of Lund Lund Berlingska Boktryckeriet 1950 Pp 156

THE title of this work immediately suggests the question "What is the matter with the method of diagnosis of cancer of the corpus of the uterus by means of the curette?" Dr Norman answers it by describing several cases in which the tissue obtained by curettage failed to reveal the presence of a malignant growth, which hystero-graphy showed to be present. He writes clearly, in perfect English and the book is profusely illustrated by reproductions of X ray pictures. Gynaecologists and radiologists not familiar with this method of diagnosis will profit by studying his technique and results.

Human Personality and Minor Disorders

WILLIAM HARROWES, M.D., M.R.C.P.E., D.P.M., F.R.S.E. Edinburgh E & S Livingstone 1949 Pp 260 15s

ALTHOUGH the late Adolf Meyer never wrote a book to embody his teachings, his pupils have repaired the omission. Of these none is more faithful than Dr Harrowes—not only to the broad principles which Professor Meyer taught, but also to his plan of exposition. The personality study which at Johns Hopkins served the purpose of self-knowledge and psychological understanding, for which a psycho-analysis is nowadays sometimes deemed necessary, is here made the basis of a general discourse on the structure of personality and its relation to experience and social demands. Determined to avoid dogmatism, scientism, dualism, excessive hypostatization, and various other failings to which dynamic psychology is prone, the author gives the impression of being thoroughly sensible rather than penetrating, safe and wise but not particularly illuminating, if his oracle is not sibylline or deceitful, neither is it far removed from what ordinary men say when called into counsel. Invaluable as Adolf Meyer's psycho-biology has been and still is to psychiatrists, its expositors should now take account of the detailed findings and rich material accumulated by other psychologists and psychiatrists since Dr Meyer formulated his working philosophy. Norman Cameron's book was a happy example of such a restatement. Dr Harrowes has been too loyal in his strict adherence to the incomparably sane and balanced teaching which in its day and for more than two decades made the Henry Phipps Clinic a nursery of psychiatrists as averse from excursions into theory as from inertia in the study and treatment of their patients.

L'Arachnoidite optique canaliculaire et orbitaire

RENE CAZABAN, assistant ophthalmologist, Montpellier Hospitals Paris L'Expansion Scientifique Française 1950 Pp 102

THE concept of optochiasmatic arachnoiditis, evolved during the past twenty years, has suggested a surgical approach to the complex problem of optic atrophy. Unfortunately, however, operative removal of adhesions around the chiasma and the intracranial portions of the optic nerve has given disappointing results. Moreover the frequency of such adhesions appears to have been overrated. Dr Cazaban seeks to extend the original concept by emphasising that the optic nerve has a

POSTSCRIPT

Since writing this paper, I have found that the non identity of the serum factor and heterophil antibody was also recognised by Waaler (1940) whose paper seems to have been generally overlooked

Medical Societies

LIVERPOOL MEDICAL INSTITUTION

Medical Services for Students

At a meeting on Oct 19, with Dr DAVID JOHNSTON, the president, in the chair, Dr R W PARNELL pointed out that the student health movement was world-wide, outside Britain and America there were known to be 58 university health services in twenty-five different countries. In 50 of these services routine chest radiography was practised, while in over two-thirds of the total a general physical examination was made. In the U.S.A. the Student Health Association, with two hundred member institutions, had met annually for over twenty-five years. In Great Britain only 4 of the 17 universities now had no whole time student health officer.

Industrial health services existed because of the advantages in providing for a group with common needs, and it would be unfair to suggest that there was no industry among 130,000 students in Great Britain. Health examinations were valuable in at least two ways: (1) they were preventive, leading, for example, to early diagnosis of tuberculosis and to better planning of study schedules and less mental strain at the time of examinations; (2) health records relating to one group with one set of occupational risks were essential to research on normal health. The importance of tuberculosis was recognised by everyone interested in the care of young adults. It was not generally recognised, however, that nervous breakdown caused far more prolonged illness in students than did tuberculosis. High recovery-rates suggested that here lay great, though often neglected, opportunity for preventive action following earlier diagnosis.

Dr V. CORROV CORNWALL said that in a medical service for students the prevention and treatment of tuberculosis had a very important place. Dr Nicholas Malleson's figures showed that about 0.2% of non-medical students, and about 1.0% of medical students, were victims of this disease. Even if they recovered, the loss of academic time was serious. The idea of a post-cure rehabilitation centre of, say, 100 beds for the country was excellent, but time and money would be needed. If, however, the regional boards and the universities would coöperate something could be done at once. All affected students should be sent for treatment to one particular hospital in each region, and the faculties to which these students belonged should guide their studies within limits set by the physician in charge. In the Liverpool region not more than 12 beds would be needed. No extra money was necessary—only good will and coöperation.

Dr R W BROOKFIELD remarked that medical care was only one aspect of the much larger subject of student welfare. Catering arrangements, means of transport, and supervision of lodgings were important for the well-being of the student and should be the responsibility of laymen working in conjunction with the medical officer. In those universities where students were supervised by a tutor, the tutor could contribute greatly to the physical and mental health of those in his care by drawing the doctor's attention to suspected abnormalities.

Dr G W TAYLOR suggested that the high incidence of anxiety state and other mental illnesses among university students might be reduced by means of the system as operated in Scottish universities. The

regent was in a position to understand mild anxiety states in the student and to give early help, thus forestalling the disability which might ensue from the undetected "pre-examination syndrome."

New Inventions

TUBAL PALPATOR FOR SALPINGOGRAPHY

THE increasing use of salpingography has led workers to experiment with solutions more rapidly eliminated than the older oil media. The introduction of such water-soluble media in the last few years has been highly successful from that point of view, but the very rapidity of elimination has brought with it some special difficulties.

Where there is considerable spasm of the fallopian tubes it is sometimes difficult, during the screen examination, to determine whether a tube is patent or not, especially if there is a dilated and tortuous tube. With oil media, the presence of the oil 24 hours later, distributed among the intestines, can be taken as positive proof of patency. This is not possible with the newer media, which are sometimes so rapidly absorbed that most of the medium is eliminated within 20 minutes. If one could delay absorption to a few hours one might, in a doubtful case, be able to see the medium dispersed in the abdomen later, but unfortunately the makers state that it is not possible so to delay the absorption of water soluble media.

On the basis of an idea put forward by Marsalek,¹ who used a wooden stick in the rectum, I have devised the plastic instrument illustrated here, which can be inserted into the rectum and carries a radiopaque marker at the tip. The instrument may be inserted into the rectum either before or during the injection of the medium. Where there is doubt about tubal patency, the tube on the left side, and quite often that on the right also, may then be manipulated and squeezed

between the pelvic wall and the instrument, when extrusion of the fluid will establish that the tube is patent. Thus the difficulties arising from rapidly absorbed media can often be overcome.

The instrument is also extremely useful in malpositions to determine fixity of the uterus or adhesions of the tubes. It can also be used to replace a retroverted uterus under the X-ray screen, to show whether reposition improves patency.

The instrument is made by Messrs Vann Bros Ltd., 63, Weymouth Street, London, W 1, to whom I am indebted for their coöperation. My thanks are also due to Miss J. Perry, official artist to the Manchester Regional Hospital Board, for the drawing.

THE LANCET

LONDON SATURDAY, NOV 11, 1950

Revolt at Kingston

ONE of the main advantages expected from the National Health Service was that the hospital services of each region would be rationally planned. To fulfil its duties, each board needs not only the courage of its convictions but also power to do, within limits, whatever it thinks necessary. If boards are to take wide rather than narrow views of hospital arrangement, they should have some protection from continual pressure either from below or from above, and at present they enjoy such protection because they are not elected bodies and because the Minister, though he often offers them advice, very seldom gives them instructions. The boards are thus in a position to exercise detached judgment, as was intended. But this detachment unfortunately carries its own risks. Freed from the need to follow public opinion, the boards may pay too little attention to it. And the more they are intent on the good of the hospitals the less they may study the good of the National Health Service as a whole, and of its other branches. These tendencies have been evident in the controversies that have arisen over the proposed extinction of small long established hospitals, such as the London Lock Hospital and Paddington Green Children's Hospital, which were convenient to the people of their neighbourhood, and over the conversion of existing general-practitioner hospitals to other purposes, as at More cambe, Felixstowe, and now Kingston upon Thames. If it were certain that the principles governing these changes were correct, we should all feel obliged to support them, despite the inconvenience caused to individuals. But in preferring large hospitals to small ones boards are applying a policy which many believe to be already outmoded, and where they deprive general practitioners of hospital beds, without adequate clinical compensation, they are acting on the ideas of five years ago rather than those of today.

The disagreement over the future of the Kingston and Malden Victoria Hospital springs from the South West Metropolitan Regional Hospital Board's decision to turn this well equipped general practitioner hospital into a gynaecological unit, thus freeing beds at the nearby general hospital for maternity cases and enabling it to give distinctly better service. Three times the management committee disputed this decision, but last summer it lost its chairman and three members who were prominent in their opposition when their term of office ended the board took the opportunity of not reappointing them, and the committee as reconstituted now supports the board. The Ministry of Health has been unwilling to interfere with the board's choice of members for the committee,¹ or with its decision on the hospital's future use.² The general practitioner staff last month received twelve days' notice to quit the hospital.

This they have not accepted, on the ground that the alternative offered—a building without lifts, operating-theatre, or adequate nurses' accommodation—is unsuitable. Nor do these practitioners regard the offer of clinical assistantships at the general hospital as sufficient recompense.

This conflict exposes more than one of the potential weak spots in the service. In the first place, hospital boards, being concerned with the efficiency of their own services rather than the future of general practice, are liable, despite the Minister's advice,³ to ignore the effect of their decisions on the prestige and quality of the family doctor's work. (It seems extraordinary that at Kingston, according to spokesmen of the "Kingston Victoria Defence Committee," the Surrey Executive Council has succeeded no better than other bodies in making its objections heard.) Secondly, a board which, seeing its resources as a whole, knows that it must be the final arbiter, may be inclined not to bother to carry public opinion with it. At Kingston and Malden, where the town councils have protested and a vigorously hostile poster campaign has been started, the South West Metropolitan Board does not seem to have taken enough pains to allay local opposition. Had there been a full and public inquiry at which all responsible parties were invited to express their views, the board's decision might still have seemed unreasonable to some, but no charge of cabalism could have been sustained. Medicine, even in hospitals, is a personal affair in which the emotions are closely engaged, and by failing to consult and convert local sentiment a board or committee may unwittingly stop people from thinking of hospitals as existing for them and belonging to them.

Early Smallpox

SINCE compulsion was withdrawn two years ago much fewer babies have been vaccinated, and the more people susceptible to smallpox there are in our population the more important it will become to recognise imported infection as early as possible. Typical cases seldom present much difficulty to the experienced clinician, but atypical cases are not rare, and this year's Glasgow outbreak illustrated how dangerous they can be. The clinician should always have his suspicions confirmed or allayed without delay by the laboratory, where the methods of diagnosing smallpox are now rapid and thoroughly reliable. What tests to apply at different stages of the infection, and the material required for them, were discussed by DOWNIE⁴ four years ago. When the first focal lesions appear, the maculopapules should be scraped with a scalpel or needle and the exudate smeared (but not fixed) on clean glass slides, the laboratory can use smears of this kind for microscopical examination, for culture on the chorio allantois of the developing chick, or as an antigen for complement-fixation tests. The smears may contain living virus, so they must be handled and packed with special care. The serological complement-fixation test for specific antigen, when done on adequate samples of scrapings from papules, on fluid from vesicles and pustules, or on crusts of dry lesions, is

course in the optic canal and in the orbit, and that in this course it is surrounded not only by pia mater but by all the layers of the meninges. Meningitis at the canal and in the orbit would therefore seem possible as a pathological entity, and he advances evidence of its existence obtained mainly by operative exposure of the optic nerve. As aetiological factors, he incriminates neighbourhood infection—e.g., of the sinuses—and general disturbances, in which the common causes of acute and chronic meningitis figure. His view that Leber's disease is secondary to this type of meningitis is hardly convincing.

Clinical Nutrition

Editors NORMAN JOLLIFFE, FREDERICK F TISDALL, PAUL R CANNON, for the Food and Nutrition Board of the National Research Council, United States of America. London: Cassell 1950. Pp 925. 90s.

THE 31 chapters of this book have been contributed singly or jointly by 36 authors, most of them well known and all of them experienced.

In the opening section on diagnosis the chapter on the clinical signs stands out by reason of the clearness of the text, the coloured illustrations, and the photographs. A detailed analysis follows of the various deficiencies that may lead to malnutrition—protein, carbohydrate, calories, and the various minerals and vitamins being discussed in turn. The vitamins are not given undue prominence, and the chapter on sodium and potassium is one of the best. The remainder of the book deals with therapy and prevention, and contains some valuable articles. Newburgh's chapter on obesity merits serious consideration, and the last chapter, on the nutritional requirements for individual work, is serviceable, and would be even better if the sections on hot and cold environments were expanded. Less happy chapters deal with rickets and calcium metabolism.

The North American point of view is not as a rule over-emphasised, but some important contributions made on this side of the Atlantic escape mention.

Cerebral Angiography

P ALMEIDA LIMA, professor of neurology, Lisbon Faculty of Medicine. London: Oxford University Press 1950. Pp 221. £2 5s.

THIS is the first textbook on this subject to appear since Professor Lima's predecessor, Prof Egas Moniz, began his work on the subject nearly 25 years ago. It will therefore be read with great interest by all concerned with the diagnosis of intracranial lesions. The text is clearly written and there is much material to illustrate vascular abnormalities and the displacements caused by intracranial lesions, together with a sound exposition of the normal anatomy of the vascular system inside the skull. But very few anteroposterior angiographic studies are shown and Professor Lima does not seem to use oblique projections. Their absence makes it more difficult for the reader to obtain a mental picture of the direction of the displacements and their source. The adherence by the writer to surgical exposure of the common carotid artery, and to 'Thorotrast' as a contrast medium, will rouse controversy. The operation has been almost universally superseded by the percutaneous method of injection, which is here briefly dismissed, and thorotrast has been discarded by most workers as radioactive and therefore potentially dangerous. Other media at present available are not without their disadvantages, and Professor Lima's arguments in favour of thorotrast will be read with interest.

The Medical Annual, 1950 (Bristol: John Wright & Sons 1950. Pp 440. 25s.)—The "annual" fully conforms to its accustomed high standard. As editors, Sir Henry Tidy and Prof A Rendle Short have had in mind almost all the advance points of medicine: surgery, obstetrics, and gynaecology, and show their usual wise caution in the acceptance of early unproved work. The illustrations are good and to the point. Among important items are first-class reviews of leucotomy by Dr E W Anderson, and of the PULHEISS medical classification by Dr R P Fletcher, there are besides many details of 'Aureomycin' Q fever, radioactive isotopes, and other current topics.

New and Nonofficial Remedies 1950 (London: J B Lippincott. Pp 800. 27s.)—This annual volume is known to British pharmacologists and manufacturing chemists as a valuable supplement to official American publications. It describes preparations and articles which have been examined and accepted by the American Medical Association's council of pharmacy and chemistry, and it also contains a list of products that have not been accepted.

Analgesia for Normal Childbirth (Oxford: Blackwell Scientific Publications 1950. Pp 19. 2s.)—This is a small guide to the use of N₂O air analgesia in the course of normal labour, and it is intended mainly for midwives. Notes are given on the construction, care, and maintenance of the standard apparatus, together with causes of failure and contra-indications to its use. The author, Dr E H Seward, holds diplomas in both anaesthetics and obstetrics and has been awarded a Nuffield scholarship for research into the relief of pain in childbirth. He discharges his present task simply and ably.

The Microscopic Diagnosis of Human Malaria (Studies from the Institute for Medical Research, Federation of Malaya. Kuala Lumpur: Government Press 1948. 5 Malayan dollars—about 15s, post free).—Dr John W Field is to be congratulated on his concise and extremely well illustrated volume, giving all the information necessary for the microscopical diagnosis of the human malaras. Both the initiate and the expert worker in the field of medicine in the tropics will value it, and so will the pathologist in this country, now so often called upon to make a microscopical diagnosis (the only effective diagnosis) in cases of suspected relapse of malaria. Speculative diagnosis and speculative treatment of malaria are generally undesirable, this book shows how they can be avoided.

Essentials of Materia Medica, Pharmacology, and Therapeutics (5th ed. London: J & A Churchill 1950. Pp 438. 21s.)—A new edition of "Micks" can always be sure of a cordial reception. The stimulating and at times combative style in which it is written arouses and maintains the student's interest. In this edition recent work receives due attention and its assimilation has been complete. In the preface to his first edition, Prof R H Micks said that he had not refrained from giving personal views on subjects when it would be cowardly not to do so, and readers will observe that his courage has not declined during the fifteen years that have since passed. It is on one or two of the issues raised in this way that criticism may fairly be made. His forthright condemnation of intravenous iron preparations, and his well known opinions on the use of glucose in diabetic coma, might have been expressed with regard to the existence of opposing schools of thought.

It is the author's aim to provide a background to the intelligent use of drugs, rather than offer extensive information about drug preparations. Nevertheless, short lists of important official preparations, placed at the ends of chapters, might make the book still more instructive.

Operative Surgery (3rd ed. London: Oxford University Press 1950. Pp 559. 30s.)—This book, intended for senior students and young-graduates engaged in surgical work in hospitals, and as a basis for those reading for higher surgical diplomas, is a summary of Edinburgh surgical practice by 24 distinguished contributors, all of whom either work or have been trained in that great school. The editors, Mr Alexander Miles and Sir James Learmonth, have made a small scale map of operative surgery, giving the general lie of the land. Its detail in text and illustration is not complete enough to help the fully fledged specialist in his specialty, or to enable those faced with unfamiliar operations to perform them. The brain, the ear, the eye, and the female genitalia are not considered, and space precludes descriptions of alternative methods of doing the operations described.

Any surgeon who reviews a book on operative surgery inevitably finds small points in technique with which he disagrees. For example, in splenectomy, the hand is a better retractor of the spleen than the retractor shown in fig 214: the angular vein should never be ligated in carbuncle of the face, and hot boracic fomentations are actively harmful as a postoperative treatment of pulp whitlows. To set against petty personal differences of opinion there are whole chapters of the first quality—e.g., that on the general technique of abdominal surgery. This book is highly recommended to those for whom it is written.

munity, and this is an aspect of medical training which, though mentioned by the Goodenough Committee,¹² is too often overlooked in the eternal discussion of technical details. It is a paradox that those boys and girls who choose a profession in which they will have to offer mature counsel on any and every human problem should be the very ones who are first diverted from the broad educational road on to the narrow path of specialisation. When, furthermore, the odds are heavily against their passing the first hurdle, and even the lucky minority cannot be sure of admission to a preclinical course, the sense of frustration among teachers and pupils alike is easily understood. The low pass-rate of London external candidates is not easy to explain. It is hardly surprising that many schools cannot offer groups of half a dozen pupils the facilities which universities can provide for classes of fifty, but when large and wealthy schools with ample resources seem to do little better than the rest, one is forced to conclude that some other factor is at work. One suggestion is that school-children of 16 are not always ready to assimilate material which 18 year-old university students absorb comfortably in a year. Schoolmasters, however, argue that the fault lies simply in the syllabus, parts of which are too wide and too vague to be covered in the time.¹³

As Mr BIRLEY observed, the examination is historically a university one, and was once an integral part of the university training in medicine. Even today many London schools prefer, and some insist, that students should attend the internal premedical course, thus permitting them to pursue a general education until they begin medicine, and ensuring continuity of medical teaching. At least one university, however, has contributed to the present unsatisfactory state of affairs by virtually abolishing premedical instruction, and so compelling schools to provide it. This retrograde step might appear justified by the Goodenough Committee's recommendation that the basic sciences should be taught at school, but the committee was careful to add that such teaching should form part of general education spread over a period of years, with no professional examination in view.¹² It went further and proposed to abolish the premedical year as well as the examination, but this would involve shortening the course and does not find much favour today. Instead, London University is now considering a plan to create an eight-term preclinical course which would be followed at medical school. This is clearly in harmony with the spirit, if not the letter, of the Goodenough report.

We believe that doctors should have the widest education which society can afford to give them. Premature specialisation tends not only to stunt personal development but also to prevent the attainment of that full professional stature which enables a man to do his best work. It is as detrimental to the profession as to the individual that the doctors of the future should begin their vocational training too early, and the fact that this training necessarily takes a long time does not justify the demand that it should start at school, at an age when the studies of other boys are still unrestricted. If the 1st M.B.

is to be retained it should become again a purely internal university examination, thus allowing candidates to complete their general education, to make their final choice of a career slightly later, and to enter medical school at an age when they are more likely to derive the greatest benefit from a very exacting training. The London University plan, as we understand it, would have all these merits, in addition to others which it is too early to discuss.

Rice Diet In Hypertension

IN the six years since KEMPNER introduced his rice diet for the treatment of hypertensive vascular disease, the large amount of work done has shown that it favourably modifies the natural course of the condition. At the same time certain disadvantages and dangers have been defined.

This week we publish a Medical Research Council report describing an English trial of the treatment. The test group was restricted to patients who, during at least ten days in hospital on bed rest, showed an average diastolic blood pressure of at least 120 mm Hg. In 35 such cases put on the rice diet the average fall of blood-pressure was 55/26 mm Hg, and of 33 patients with symptoms referable to hypertension 25 obtained relief. These results agree remarkably closely with those reported by WATKIN *et al*¹ in 50 patients with advanced essential hypertension. In both series not only was the blood-pressure lowered, and symptoms relieved, but improvement was sometimes apparent in the size of the heart, the condition of the retina, and the electrocardiographic findings. These and other reports provide convincing evidence that the beneficial effect is largely, if not wholly, due to the very low sodium content of the diet (less than 200 mg per day). The administration of sodium chloride, or even transfer to a conventional low-sodium diet (less than 2 g per day), results in a steady rise in blood pressure though not necessarily the reappearance of symptoms. The American workers noted a decline to normal of the blood cholesterol², but, while regarding this as a step in the right direction, they felt unable to state whether it had any significant effect on the course of the disease. On the question whether nitrogen balance can be achieved on this diet, the M.R.C. report states that the 3 patients in whom this factor was observed were still in slightly negative balance at the end of six weeks, the American report, while confirming this observation in the early weeks of treatment, found that the nitrogen deficit diminished later and that virtual balance was eventually reached in some cases. This point was studied by DOLE *et al*³ who found that equilibrium was reached in three to five months, with larger subjects taking the longer time.

Now for the disadvantages. The treatment has one real danger in that such extreme salt reduction depresses the glomerular filtration rate and to a less extent tubular reabsorption. Impaired renal function was observed by McCANCE⁴ in normal subjects during salt starvation and has been noted by several investigators of the rice diet, in fact one patient

the most generally useful, for it is almost invariably positive in true cases of smallpox, and with it a laboratory report can be given in a day. Egg culture of material from the focal lesions at any stage of development is the most certain method, but the smallpox virus takes 2-3 days to produce lesions on the chorio allantois which can readily be distinguished from those of vaccinia virus. These methods have proved their worth in years of routine practice, in the second of the two papers on smallpox in this issue, Dr MACCALLUM, director of the Medical Research Council's Virus Reference Laboratory, and two clinical colleagues, discuss their ways of applying them and confirm their reliability. A different test has been investigated by COLLIER and SCHONFELD⁵ in Indonesia, where they have examined more than 2000 samples of serum from cases of variola for anti-haemagglutinins to the virus. This test established the diagnosis in some cases on the fifth day of illness, but the titre of antibody reaches its maximum 7-10 days later, when complement-fixing antibodies may also be present in the patient's serum. Though less useful in the early stages of the disease, this may be a valuable ancillary test where egg culture is impracticable. Vaccination also gives rise to serum anti-haemagglutinins, but this is said not to be a serious source of confusion.

The work of FENNER⁶ on experimental ectromelia in mice reminds us how little we know about the pathogenesis of some of the common exanthems. There seems little doubt that the virus spreads from one patient to another directly by the respiratory route, though DOWNIE and DUMBELL⁷ showed that in closed communities infected dust may play a part in dissemination. Many clinicians hold that smallpox is infectious in the febrile period before the exanthem develops, but others deny this. MACCALLUM and his colleagues support the view that variola virus is inspired into the lung, where a primary focus develops, eventually involving the capillaries and giving rise to the viraemia and perhaps also enabling virus to reach the bronchial secretions. On the analogy of FENNER's findings in ectromelia one might expect to find an initial focus as the source of the primary viraemia, but this speculation has still to be backed by evidence, for recovery of the virus from the lung of a fatal case means very little. If smallpox is infectious in the pre-eruptive stages one might expect virus to be recoverable from throat swabs or tracheo-bronchial secretions, but in neither of the present investigations were attempts successful. It is more likely that smallpox becomes infectious only when the focal lesions that appear early on the mucosa of the oropharynx discharge their virus into the secretions. Professor DOWNIE and the two members of his department in Liverpool noted that on the third day of illness one of their patients had only a faint macular rash on the face though there were 8 well-developed lesions on the dorsum of the tongue. More attention might be given to the time relations of the appearance and development of lesions on the mucosa and on the skin.

A striking feature of the clinical course of smallpox is the rapid disappearance of severe prodromal

symptoms as the rash comes out. It seems certain that the virus is present in the blood stream in the early febrile stages, and both groups of investigators have recovered the organism from the blood. It may be objected that five of the six positive blood cultures came from patients who were so severely infected that they died soon afterwards, but virus was also recovered from the blood of one of the moderately severe Liverpool cases on the first day of illness though not on the second. The fall in temperature and general improvement in the average patient as the rash comes out is explained by the rapid appearance of neutralising antibody, whereas severe haemorrhagic cases do not develop enough antibodies to cope with a massive invasion. The transient viraemia in moderately severe cases may also be explained on the time relations of virus liberation and antibody production. There are no grounds for believing that virus is disseminated to the skin before the temperature rises, and DIXON's⁸ careful clinical observations in North Africa support the contrary view. The sudden flooding of the blood stream with virus and its almost equally sudden suppression might form a basis for the use of blood cultures in smallpox diagnosis, and this method might make a very early diagnosis possible in contacts who are under close supervision.

A Controversial Examination

THE Headmaster of Eton was on firm ground when, as we reported last week, he attacked the growing practice of taking the 1st M.B. at school. He held that this encourages premature specialisation at the expense of the broader education which the General Certificate is designed to promote, and he pointed out that the examination is acting as a filter in selecting the future members of the medical profession—a filter which often fails to pass students who have been very carefully chosen for admission to a medical school.⁹

Mr BIRLEY was speaking at a meeting of the Royal Society of Medicine, and his views apparently met with the approval of his audience, at least, they were not seriously opposed. The thesis that the 1st M.B. has a selective function has in the past been disputed by a London University examiner¹⁰, but every examination is selective in direct proportion to the failure rate among those attempting it, and the failure rate among candidates for the London external 1st M.B. is said to be about 85%. The argument in favour of sitting this highly selective examination at school has been presented in our columns by Dr HAROLD SCARBOROUGH,¹¹ but even he envisaged a change in its form. His argument was based on the student's need to acquire a "secure foundation in science" before entering a medical school, but he did not explain precisely what he meant by a "secure foundation" science to School Certificate or matriculation standard might well be so described. There must be many schools which can easily provide instruction up to this standard but which find tuition for the 1st M.B. an undue strain on their resources.

A sound liberal education is at least as important to a doctor as it is to any other member of the com-

rheumatoid sera but not with normal sera however, the positive reactions with the rheumatoid sera occurred as frequently with the "normal" antigen as with the antigen from rheumatoid tissue, so that the experiments lend no support to the hypothesis of an altered connective tissue acting as an antigen

Whether these two reactions are in any way directly related cannot yet be said. It has become clear that a large number of the "colloidal reactions" in hepatic disease are all essentially modified tests for the presence of increased quantities of γ -globulin and it seems equally likely that many of the reactions observed in rheumatoid arthritis may be found eventually to be due to some common factor. The rapid progress in the study of the disease with Cortisone and A.C.T.H. makes it likely that an answer will be discovered sooner rather than later.

ACROSS THE CHANNEL

ONE of the objectives of the Brussels Treaty is "to develop on corresponding lines the social and other related services" of the five countries of Western Union. In public health a beginning has been made with personal contacts between officials and exchange of information.

Dr N. M. Goodman in his Chadwick lecture of Oct. 24, sketched the public health administration of Belgium, France, Luxembourg, and the Netherlands, and pointed to some of the differences from our own. The French and Belgians, he said, regard administration as a science, the British regard it as an art (or even a craft), and the Dutch are somewhere between the two. In other words, the Franco-Belgian approach is logical and sometimes (in British eyes) unpractical, the British approach is practical and nearly always illogical. The Dutch tradition of individual and local self-reliance has tended towards a conservation of voluntary effort in public health as well as other fields, the French, and to a lesser extent the Belgian, systems owe much to the Napoleonic concepts of the *droit administratif* and of centralisation, while the British tradition of sanitary reform has fixed the broad lines of our public health system on a local basis. Except in the older and larger municipalities (where he is sometimes a part-time clinician) the M.O.H. in the other Western Union countries is generally an employee of the central government, responsible to the prefect or governor of his department (country) as well as to the local municipal council. In France each department has a full-time director of health. In all the countries, except ours, doctors and other technical health staff are eligible for, and in fact hold, executive positions on a par with those of lay administrators: thus in France, Belgium and the Netherlands the permanent heads of the health ministries are doctors, and so are the directors of most of the divisions dealing directly with health. In Britain, of course, doctors in central health departments are advisory not executive, but Ethiopia said Dr Goodman, "I believe the only other country in the world, including the Dominions which follows our example." Perhaps we are too apt, he added, "to think of something as strange and peculiar because we do not do it ourselves whereas inquiry will show that it is we who are peculiar and in a minority." In public health the convergent development aimed at by the Brussels Treaty will be attainable only if we begin by knowing something about the organisation in the other Western Union countries.

Dr Goodman also had some cogent things to say about instruction in public health. His impression is that the instruction of undergraduates in this subject is more thorough on the Continent than in some at least of our own schools. For postgraduates we have had a statutory course and diploma controlled by the General Medical Council for 64 years whereas in the other countries uniformity of standards has only lately been introduced.

"On the other hand the creation of a French National School of Public Health in 1947 in Paris, and the striking fall in the number of D.P.H. students in this country since 1948, make it look as if we were in some danger of losing our longstanding lead in public health training. Indeed, unless the position here changes—as no doubt it will—we may find it impossible to fill the vacancies for public-health medical officers, which is already causing difficulty in the central services."

TISSUE STAGE OF MALARIA PARASITES

THE existence of tissue forms of the malaria parasite in man and other mammals had been postulated for twenty years before Shortt and Garnham in 1948 located the long sought parasites in the parenchyma cells of the liver, where they were unexpectedly large. They were demonstrated first with *P. cynomolgi*¹ in monkeys, and then with *P. vivax*,² and lastly *P. falciparum*³ in biopsy specimens from volunteers. These discoveries were acclaimed by malarialogists throughout the world, but a dissenting voice has now been raised by Dr Clav G. Huff, one of the leading American parasitologists, who has done classical work on the development of the sporozoites of avian malaria through cryptozoites in the reticulo-endothelial cells to reach the familiar forms in the red cells. In a letter published in America Huff⁴ points out that no one has yet demonstrated the stage connecting the sporozoites with the forms found in the liver four days later. Material supplied by Shortt has been fixed and stained by Huff's methods and Huff has found differences between the bodies that Shortt described and the recognised forms of the avian and saurian plasmodia. He concludes that "there seems to be no alternative to doubting the malarial nature of the bodies described by Colonel Shortt and his collaborators." He does not deny that these bodies may be exoerythrocytic forms of malaria, but he urges that much more work is needed before the claim can be considered proved.

Further research, particularly into the development of the sporozoites during the first four days, is certainly desirable, but there are good reasons for expecting it to confirm the claim. The objects seen in liver sections when fixed with Carnoy and stained with Giemsa, are fundamentally similar to the tissue forms of avian malaria, though Huff's technique of fixing in Zenker-formol and staining by Maximow's method has led to different results. Then the ripening into merozoites on the 8th to 10th day (*P. cynomolgi*) fits exactly with the time at which the blood first becomes infective on subinoculation. Moreover, the findings of Shortt and Garnham with *P. cynomolgi* have been completely confirmed, on different material, at the National Institute for Medical Research.⁵ The appearance of the parasites with only a single generation between the sporozoite and the forms in the blood agrees with the fact that liver tissue (even if it contains parasites) does not become infective on subinoculation until the 8th day. Large numbers of human liver sections, taken at necropsies have been diligently searched as controls and have not yielded any objects resembling those found by Shortt and his colleagues in their biopsies taken from the volunteers just when the presence of the pre-erythrocytic forms had been foretold. One may therefore safely predict that future work will remove even the last lingering doubts.

mentioned in the MRC report died of uræmia while under treatment. It appears that a kidney already damaged by hypertensive disease may be unable to conserve sodium chloride, with resulting dangerous hypochloræmia, so, if the urinary sodium or chloride does not fall to a low level within a few days of starting the diet, blood urea and blood sodium must be carefully observed. Indeed it seems, on the evidence to date, that renal failure is an absolute contra indication to sodium starvation. A quite unexpected and severe complication encountered by WATKIN and his colleagues was the activation of peptic ulceration in patients who had previously had ulcers. They attributed it to the acid fruit juices, roughage, and perhaps the low protein content of the rice diet. The biggest disadvantage, however, is the unpalatable monotony of the diet. To practise it at all requires a high degree of cooperation between patient, physician, and dietitian, and a proportion of patients will not tolerate it at any price. Though

some measure of success has been achieved with outpatients in America, rationing and related dietetic difficulties make it less likely that in this country it could be successfully used outside the metabolic ward.

Nevertheless, on the purely experimental side the rice diet is a development of great promise. It offers a new approach, or rather it suggests that an old approach was after all important, for it is only just to recollect that forty-five years ago AMBARD and BEAUJARD⁵ propounded the theory that hypertension results from the retention of sodium chloride. Imagination readily spins a web of association. We now know that the hypotension of Addison's disease can be mitigated with sodium, that the oxytocin can check the sodium wastage and raise the blood pressure even to abnormal heights, and that the presence of cortical suprarenal tissue is essential to the experimental hypertension of the Goldblatt clamp. Sodium is coming into its own—*natrum redivivum*.

Annotations

GEORGE BERNARD SHAW

A GENERATION which has carried two world wars and not unreasonably expects further calamities has had its compensations, and not the least of these has been the fearful joy of living alongside Mr Shaw. All our lives he has been inviting us to laugh and think—not occasionally or slightly, but as though the fountain of his hospitality would never run dry. When he came into his powers, in the '90s, accepted forms and standards had not been examined closely for the best part of a century, and it was still possible to be smug about progress. Into this sleeping palace Shaw burst like a poltergeist into the Athenæum, tossing the furniture about seemingly at random. Looking back it is clear that there was nothing random about it, though he ranged widely in his attacks against stupidity, the method has always been the same. He decided what he was going to say and then said it as provocatively and amusingly as he knew how. And he knew how. The characters in his plays are said to be puppets all talking Shaw, but the effect is never of a puppet show, for a world peopled by a race of Shaws is inevitably livelier than a world peopled by the rest of us. It was a device which enabled him to argue on both sides, and since he was a glorious debater his audiences, whatever the individual opinions among them, had the sensation of giving hard knocks as well as taking them. This is not to say that he was always either fully informed or fully scrupulous in presenting evidence in attacking animal experiment, for example, he took the untenable line that no good has ever come of it, and in his robust assault on the medical profession in *The Doctor's Dilemma* he made no serious attempt to be fair. It does not matter in the least the argument is the thing, the argument which goads and delights and provokes the mind into wakefulness. Though science was one of his favourite cockshies he preached a curiously scientific message: nothing is to be taken on trust, nothing must be regarded as proven for good, opinion must never be confused with fact, or prejudice with principle. He never pretended to know all the answers, he was, as he said in *Too True to be Good*, a preacher, and the business of a preacher is to preach. "You are reasoning animals," he seems to say again and again, "for heaven's sake use your reason." It is an exacting doctrine, and one which seems to take no account of the hidden springs of our behaviour. Yet in *Man and Superman* his analysis of the complementary drives in men and women runs

very close to the views which Freud was achieving by a less intuitive process.

To Shaw social justice seemed not so much a moral ideal as a common sense necessity (his only interest in the poor, he said, was to abolish them), and this unsentimental approach brought him a reputation for sparkling coldness, which those who knew him personally knew well was undeserved. The high spirit—and high spirits—which kindled the Fabians and helped to set in train the social reforms of our century (he has lived to see most of the poor abolished in this country) lasted him to the end.

SERUM FACTORS IN RHEUMATOID ARTHRITIS

THOUGH patients with rheumatoid arthritis show certain changes commonly found in chronic infections—such as increased sedimentation rate, leucocytosis, and alteration in serum protein—no infective agent has been found, and the cause of these changes is still unknown.

In this issue Dr Ball describes careful studies of the phenomenon first described by Rose et al.¹ in 1948, when it was found that the serum of patients with rheumatoid arthritis agglutinated sheep cells sensitised with a rabbit anti sheep cell serum. The agglutinin was not the common heterophil antibody, and was not removed by absorption with unsensitised cells. Ball reports that of 895 cases of various types the reaction was found positive in 153, and of these 140 were cases of rheumatoid arthritis; the remaining positive reactions were all in cases of arthritic disease, not diagnosed as rheumatoid arthritis, and included 3 examples of disseminated lupus erythematosus and 1 of dermatomyositis. Of 134 non arthritic patients, not one gave a positive reaction. The "serum factor" responsible for this reaction—and Ball is careful not to call it an antibody—is entirely unknown, but it seems to be closely associated with the group of "collagen diseases".

Lansbury et al.² have tackled the question whether some of the changes in rheumatoid arthritis are due to the connective tissue being altered in some way, and thereby acting as a foreign substance and leading to antibody formation. They prepared antigens from rheumatoid material—i.e., rheumatoid nodules and rheumatoid joint material—and from normal joint material, and carried out precipitin and complement-fixation tests. The latter led to no clear results. Positive precipitin reactions were obtained with a number of

B C G VACCINATION OF NURSES AND STUDENTS IN EDINBURGH

H G H. HOUGHTON N W HORNE
MB Edm., M.R.C.P.E MB Edm., M.R.C.P.E

From the Tuberculosis Service of the South-Eastern Regional Hospital Board, Scotland, and the Department of Tuberculosis, University of Edinburgh

SINCE the start of the scheme of B C G vaccination in Edinburgh, 1350 hospital nurses and 1302 medical students have been tuberculin tested, and of these, 221 nurses and 208 students have been vaccinated with B C G. The nurses were tested at sixteen general and special hospitals, but not at tuberculosis hospitals since tuberculin testing is there a routine measure. The students were drawn from the university, the school of medicine of the Royal Colleges, the dental school, and the Royal Dick Veterinary College.

ORGANISATION

Because mass tuberculin testing and B C G vaccination had not hitherto been done in this country, certain difficulties were envisaged. The policy was that all persons tested or vaccinated should be volunteers, no compulsion being used. It was essential therefore to gain the confidence and full co-operation of all concerned. The main obstacles anticipated were

- 1 Hostility by the individual, parent, or guardian to tuberculin testing or B C G vaccination.
- 2 The difficulty experienced by hospital matrons in releasing staff from duty during the present shortage of nurses. In addition, nurses might have difficulty in reporting on account of sickness, days off, holidays, or night duty.
- 3 Failure to report for reading of the tuberculin test.
- 4 The necessity for a negative reactor, who was given B C G and again tuberculin tested, to attend at least five times and usually six or more times.

The following procedure was adopted

(a) Preliminary personal interviews with medical superintendents, matrons, and professors and lecturers resulted in their full co-operation. Prof. Charles Cameron, who inaugurated the vaccination scheme, gave short talks to each group two days or so before tuberculin testing was to be done, explaining in simple terms the significance of tuberculin testing and the object of B C G vaccination. This did much to dispel fears about B C G.

(b) Nurses were tested at the hospital at a time chosen by the matron. Sometimes this would mean visits at 8 A.M. or 9 P.M. in order to include day and night staff. At smaller hospitals usually four visits were necessary to complete the testing, but at one large teaching hospital it was necessary to make fourteen short visits to complete the testing of 170 nurses, the only suitable times being immediately after meals. Particulars were entered in books by a secretary, and each individual was handed a card with the book number and instructions where and when to attend for reading.

(c) Students attended the mass-radiography centre. Each student received a letter giving him a time of attendance. His chest was radiographed and he was tuberculin tested and then handed a card stating where and when to return. Those who failed to return received postcards asking them to report immediately.

(d) The necessity for B C G vaccination was explained to each negative reactor, and written consent was sought. If under 21 years of age the individual was asked to address a letter to the parent or guardian. This letter, signed by the matron or by the senior physician to the students' health service, explained the nature of B C G and requested authority for vaccination.

METHOD OF TUBERCULIN TESTING

The Mantoux test was used, the initial dose being 0.1 ml. of a 1 in 1000 dilution of Koch's old tuberculin (0.1 mg.), freshly prepared standard human tuberculin,

made by Messrs. Burroughs, Wellcome & Co., was used. The test was read in 48-72 hours, and, if it was negative, 1 mg. was given. The initial dilution of 1 in 1000 was used because, although we anticipated some severe reactions, we hoped, by eliminating those who would fail to react to a weaker strength, to reduce the number of attendances—there is great difficulty in reassembling students and nurses. For the result to be recorded as positive, the area of induration had to be at least 5 mm in diameter. The following grading was adopted:

Diameter of indurated area (mm)	Reaction grade
5-9	+
10-19	++
20 or more	+++

TUBERCULIN TESTING

No attempt has been made to subdivide the groups by sex or by country of origin, or to include information on contact or previous history of tuberculosis. Approximately 70% of the students and 70% of the nurses were Scottish.

Up to the end of March, 1950, 77.4% of all students investigated and 76.6% of all hospital nurses had volunteered for tuberculin testing. The hospital establishments included 1124 student nurses, who constituted

TABLE I—TUBERCULIN REACTION STATE OF STUDENTS AND HOSPITAL NURSES (ALL AGES AND ALL YEARS OF TRAINING)

Group	Total tested up to March 31 1950	Reaction to 0.1 mg. or 1 mg. o.t.			
		Positive		Negative	
		No.	%	No.	%
Students	1302	1075	82.6	227	17.4
Nurses	1350	1115	82.6	235	17.4

64.8% of the total nursing staffs. From table III it will be seen that the number of nurses tested in the first four years of training was 928, and these constituted 69.5% of the total tested. The majority of those not tested were in the older age groups, and were people who either refused testing or were not interested in the scheme. In some hospitals very few sisters presented themselves for testing, and the best response was obtained from the nurses when the matron and senior sisters volunteered.

Table I shows that of the total number tested 82.6% gave positive reactions, the percentages for nurses and students being the same. These figures are similar to those obtained in the Prophit survey (1948).

Table II shows that the incidence of tuberculin sensitivity, as is well known, increases with age, but there is

TABLE II—TUBERCULIN SENSITIVITY RELATED TO AGE*

Group	Age (years)	Total tested	Positive to 0.1 mg. or 1 mg. o.t.		Negative to 1 mg. o.t.	
			No.	%	No.	%

	—	1350	1115	82.6	235	17.4

* The figures in this table are the result of the combined influence of age and occupational risk.

CANCER REGISTRATION

In England and Wales, as in France and Denmark, an attempt is being made to secure registration of all cases of cancer. A start was made by the Radium Commission in 1930, and the Cancer Act of 1939 included some provision for records. The present undertaking was initiated in 1945, and since 1947 the General Register Office has acted as the central statistical bureau. Dr Percy Stocks, the chief medical statistician, now reports¹ that by 1948 about half the new cases of cancer were being recorded. The task is not easy: sometimes patients cannot be traced for follow up purposes, and so the General Register Office has arranged to notify the registering centre of the date and cause of death of a registered cancer patient, registration of patients treated privately may not be readily secured, and confusion may follow from a patient registering at one centre and later receiving treatment elsewhere. Since hospitals cannot fail to see the value of this work, the co-operation necessary for full registration will no doubt be forthcoming. One of the most important benefits will be a balanced view of different methods in different hands. In Dr Stocks's words "besides knowing the best results obtainable by radiotherapy and by surgery, we want to know the average prospect for patients living in different regions of the country who are receiving such treatment as is available to them in respect of cancer of each site."

B C G VACCINATION

OFFICIAL trials of B C G vaccine have started only lately in Britain, but for some time previously work had been proceeding here and in Ireland. A reminder of this is given by Dr Houghton and Dr Horne, whose report from Edinburgh appears elsewhere in this issue, and to the names they mention might be added those of Price² and Dunlevy,³ of Dublin, and Purser,⁴ of Belfast.

All these workers agree that B C G vaccination is safe. Their results cannot yet be assessed, but at the time they reported not one of all those vaccinated—about 2500 in all—had contracted tuberculosis. Dunlevy encountered one axillary abscess in a thousand vaccinations, and Purser two in a similar series, while Wallgren⁵ reports an average of only one abscess each year in Sweden. In Edinburgh there have been no such complications, and the number of defaulters may perhaps be partly explained by the local reactions of 20 mm and over which developed in 8.9% of the nurses during the preliminary Mantoux testing. If it was impracticable to give each of the customary three doses of 1, 10, and 100 μ U, it might have been wiser to omit the second rather than the first. The conversion rate was satisfactorily high in all these series except one. The figures are: Price, 100%; Dunlevy, 99.8%; Purser, 99.8%; Houghton and Horne, with vaccine "A" 100%, and with vaccine "B" 96%. These last two results suggest that not all strains of B C G are alike in their sensitising properties, especially as vaccine "B" was being used in double strength. Attention has been drawn to morphological difference between two other strains by van Deinsen et al.,⁶ according to whom the French B C G grown by Calmette's technique measures 3 μ in length, while the Danish strain grown throughout on Sauton's medium is now only 2 μ in length and is proportionately diminished in its other two dimensions. This means that, weight for

weight, the Danish B C G contains more than three times as many organisms as the French.

Further reports from Edinburgh will be especially interesting for their description of the reversion rate twelve months after vaccination with the two strains. The work carried out so far should warn vaccinators that if they use vaccines from different sources they must be prepared for different reactions and results.

INTERNATIONAL COURSE IN AUDIOLOGY

A SUCCESSFUL course of instruction in audiology—the science of hearing—was held in Stockholm from Sept 11 to 20 under the chairmanship of Prof Gunnar Holmgren. The first of its kind ever held, this International Course in Audiology was opened by H R H Princess Sibylla of Sweden in the presence of 258 participants, of whom 34 came from Great Britain. On the opening morning there were introductory lectures by Professor Holmgren, Dr Julius Lempert, and Mr Terence Cawthorne. In all, 24 countries were represented, and the 258 included 41 teachers from 13 countries. The course of instruction was divided into lectures in four parallel series, there being some eighty in all, and five practical courses, or seminars, on audiometry and hearing aids, hard of hearing children, basic audiology, and temporal bone surgery with especial reference to the fenestration operation. These were so arranged that each participant could attend two practical courses each day in addition to three lectures. Films, demonstrations at the Royal Institute of Technology, and demonstrations of operations by Prof Torsten Skoog and Dr Paul Frenckner at the Karolinska and the Southern Hospitals were also arranged. There was also a visit to the new ear, nose, and throat clinic at Uppsala which is under the direction of Prof C O Nylen.

At a banquet in the famous Town Hall on Sept 16, many tributes were paid to the organising committee and to its chairman, Professor Holmgren, whose reputation and personality had attracted such a large attendance. Already arrangements for another course are being considered.

REGISTRARS' TOCSIN

IN England and Wales the number of registrar posts is at last to be brought into line with the likely number of consultant vacancies. According to the Ministry of Health, whose statement is summarised on a later page, senior registrars and registrars each number at present upwards of 1400, and the totals are to be reduced as soon as possible to the region of 600 for senior registrars and 1100 for registrars. For these doctors this is grim news—but exactly how grim will be known only when the review of numbers by specialists is completed in the New Year. A survey in Scotland¹ showed that whereas the consultant openings, relative to registrar numbers, were numerous in some fields, such as radiodiagnosis, psychiatry, and tuberculosis, they were very few in others, such as general and orthopaedic surgery, and these differences will no doubt be acknowledged in settling the distribution of registrarships within the new total establishment. This sorry business may at least lead to a stronger link between consultants and general practitioners, for the Ministry suggests that where someone else must replace a senior registrar, a suitably qualified practitioner may be appointed as clinical assistant.

Dr ANGUS MACRAE has been appointed secretary of the British Medical Association in succession to Dr Charles Hill, M P. Dr Macrae, who is a graduate of Edinburgh University, has been an assistant secretary of the association since 1935 and deputy secretary since 1948.

B C G VACCINATION OF NURSES AND STUDENTS IN EDINBURGH

H G H. HOUGHTON

N W HORNE

M.B. Edin., M.R.C.P.E.

M.B. Edin., M.R.C.P.E.

From the Tuberculosis Service of the South-Eastern Regional Hospital Board, Scotland, and the Department of Tuberculosis, University of Edinburgh

SINCE the start of the scheme of B C G vaccination in Edinburgh, 1350 hospital nurses and 1302 medical students have been tuberculin tested, and of these, 221 nurses and 208 students have been vaccinated with B C G. The nurses were tested at sixteen general and special hospitals, but not at tuberculosis hospitals since tuberculin testing is there a routine measure. The students were drawn from the university, the school of medicine of the Royal Colleges, the dental school, and the Royal Dick Veterinary College.

ORGANISATION

Because mass tuberculin testing and B C G vaccination had not hitherto been done in this country, certain difficulties were envisaged. The policy was that all persons tested or vaccinated should be volunteers, no compulsion being used. It was essential therefore to gain the confidence and full co-operation of all concerned. The main obstacles anticipated were

- 1 Hostility by the individual, parent, or guardian to tuberculin testing or B C G vaccination
- 2 The difficulty experienced by hospital matrons in releasing staff from duty during the present shortage of nurses. In addition nurses might have difficulty in reporting on account of sickness days off, holidays, or night duty
- 3 Failure to report for reading of the tuberculin test
- 4 The necessity for a negative reactor, who was given B C G and again tuberculin tested, to attend at least five times and usually six or more times

The following procedure was adopted

(a) Preliminary personal interviews with medical superintendents, matrons, and professors and lecturers resulted in their full co-operation. Prof. Charles Cameron who inaugurated the vaccination scheme, gave short talks to each group two days or so before tuberculin testing was to be done explaining in simple terms the significance of tuberculin testing and the object of B C G vaccination. This did much to dispel fears about B C G.

(b) Nurses were tested at the hospital at a time chosen by the matron. Sometimes this would mean visits at 8 A.M. or 9 P.M. in order to include day and night staff. At smaller hospitals usually four visits were necessary to complete the testing but at one large teaching hospital it was necessary to make fourteen short visits to complete the testing of 170 nurses, the only suitable times being immediately after meals. Particulars were entered in books by a secretary and each individual was handed a card with the book number and instructions where and when to attend for reading.

(c) Students attended the mass radiography centre. Each student received a letter giving him a time of attendance. His chest was radiographed and he was tuberculin tested and then handed a card stating where and when to return. Those who failed to return received postcards asking them to report immediately.

(d) The necessity for B C G vaccination was explained to each negative reactor and written consent was sought. If under 21 years of age the individual was asked to address a letter to the parent or guardian. This letter signed by the matron or by the senior physician to the students' health service explained the nature of B C G and requested authority for vaccination.

METHOD OF TUBERCULIN TESTING

The Mantoux test was used, the initial dose being 0.1 ml. of a 1 in 1000 dilution of Koch's old tuberculin (0.1 mg.), freshly prepared standard human tuberculin,

made by Messrs Burroughs, Wellcome & Co., was used. The test was read in 48-72 hours, and, if it was negative, 1 mg. was given. The initial dilution of 1 in 1000 was used because, although we anticipated some severe reactions, we hoped, by eliminating those who would fail to react to a weaker strength, to reduce the number of attendances—there is great difficulty in reassembling students and nurses. For the result to be recorded as positive, the area of induration had to be at least 5 mm in diameter. The following grading was adopted

Diameter of indurated area (mm)	Reaction grade
5-9	+
10-19	++
20 or more	+++

TUBERCULIN TESTING

No attempt has been made to subdivide the groups by sex or by country of origin or to include information on contact or previous history of tuberculosis. Approximately 70% of the students and 70% of the nurses were Scottish.

Up to the end of March, 1950, 77.4% of all students investigated and 76.6% of all hospital nurses had volunteered for tuberculin testing. The hospital establishments included 1124 student nurses, who constituted

	22-23	163	146	89.9	17	10.1
	24-25	113	101	89.4	12	10.6
	26+	436	415	95.2	21	4.8
	—	1350	1115	82.6	235	17.4

* The figures in this table are the result of the combined influence of age and occupational risk.

here the additional factor that those whom we have tested undergo a definite occupational risk. In those up to 17 years of age the incidence of tuberculin sensitivity is low, particularly among the nurses (55.3%). In the 24-25 age group the percentage of nurses who are positive rises to 95.2. Students show, at successive ages, a similar increase in the percentage of positive reactors, which rises from 65.5 at 17 years of age to 94.4 in those aged 26 and over.

The numbers in the 17 year age group are small, but it seems that students in the group investigated (80% of whom were medical) and young nurses entering hospital in Edinburgh have lower tuberculin sensitivity than those included in the Prophit survey (1948). In this survey the percentage of positive reactors at the age of 17 was 81.4 of students and 71.8 of "other nurses".

Table III shows the tuberculin reaction related to year of training. In both nurses and students the percentage of positive reactors rises with successive years of training, but the rate of this increase differs in the two groups. In students, between the 1st and the 2nd years there is

TABLE III—TUBERCULIN SENSITIVITY RELATED TO YEAR OF TRAINING

Group	Year of training	Total tested	Positive to 0.1 mg or 1 mg O.T.		Negative to 1 mg O.T.	
			No.	%	No.	%
Students	1	245	180	77.1	56	22.9
	2	234	182	77.8	52	22.2
	3	315	258	81.9	57	18.1
	4	269	233	86.6	36	13.4
	6	234	208	88.9	26	11.1
	6+	5	5	100.0	0	0
	—	1302	1075	82.6	227	17.4
Nurses	1	444	318	71.6	126	28.4
	2	153	118	77.1	35	22.9
	3	170	139	77.7	40	22.3
	4	152	135	88.8	17	11.2
	5	25	23	92.0	2	8.0
	6+	397	382	96.2	15	3.8
	—	1350	1115	82.6	235	17.4

little change (0.7%), but between the 2nd and 3rd years there is a big increase (4.1%), and between the 3rd and 4th years a still greater increase (4.7%). In nurses there is an immediate increase of 6.5% in the 2nd year, a very small additional increase in the 3rd year (0.6%), and a big increase in the 4th year (11.1%).

From these figures it appears that, as might be expected, the student in his earlier (preclinical) years is less exposed to infection than is the student nurse. Both groups show a greater conversion rate between the 3rd and 4th years of training.

The student group included 90 dental and 172 veterinary students. During the first two years of training both these groups study subjects similar to those taken by 1st-year and 2nd-year medical students, and, like medical students, they start clinical work in the 3rd year.

Table IV shows that of those tested initially with 0.1 mg, 4.8% were negative to 0.1 mg but positive to a later dose of 1 mg. This is important, because 3 students

Total no. of negative reactors	236	227	462

and 7 nurses who were included as negative reactors were in fact negative to 0.1 mg only. They had failed to report for reading of the second Mantoux test (1 mg).

Severe reactions and complications.—Of 1097 students and 1052 nurses tested initially with 0.1 mg, 78 students (7.1%) and 90 nurses (8.9%) had local areas of induration of 20 mm or more. One nurse was off duty for three days suffering from pyrexia and complaining of a stiff arm. Most stated that there was slight irritation and slight tightness of the skin at the site of injection. For this reason, those nurses who worked in operating theatres had their injections into the skin over the deltoid region.

In 2 instances chronic skin disease was exacerbated within two weeks of the Mantoux test—one case was of psoriasis in a nurse, and the other of generalised dermatitis in a student. The nurse was Mantoux positive (+) to 0.1 mg, the student was negative to 0.1 mg but gave a ++ reaction to 1 mg.

Despite a few severe reactions, we feel that we were justified in commencing with 0.1 mg rather than with weaker dilutions, since the use of this dose reduced considerably the number of attendances.

BCG VACCINATION

Of the 462 people who did not react to tuberculin, 429 (92.9%) have been vaccinated with BCG. The percentage of nurses (94%) is slightly higher than that of students (91.6%). Altogether 4 students and 10 nurses (3%) were not vaccinated because of refusal by the responsible person to consent to vaccination, 3 of these nurses have since been vaccinated as permission was subsequently given (see table V).

TABLE VI—PARTICULARS OF THE TWO VACCINES USED

Vaccine	Volume injected (ml)	Strength (mg per ml)	Dose (mg)
A	0.1	0.50	0.05
B	0.1	1.00	0.10

From table V it will be seen that of 462 persons, 10 (4.1%) failed to come for BCG vaccination after preliminary tuberculin testing, and of 344 who were vaccinated, 27 (7.8%) did not return for subsequent tuberculin testing. In both instances the proportion of defaulters was higher in students than in nurses—6.6% compared to 1.7%, and 15% compared to 1.6%. This difference is probably due to three factors: (1) the majority of nurses live in hospital and can be brought together more easily than students who live at home, in lodgings, or in outside hostels; (2) the nurses underwent the tests at their place of work, whereas with students this was rarely possible since they are so scattered; and (3) the initial tuberculin test, the subsequent BCG vaccination, and the final tuberculin test involve several attendances spread over about nine weeks, causing greater difficulties to the student. It is unlikely that these problems will

use in the future as the nurse and student will be tuberculin-tested, and if necessary vaccinated with BCG, entry to hospital or university

Technique—The intradermal method was used throughout. The site of inoculation was the area of the outer surface of the left arm above the level of insertion of the deltoid muscle. A no. 26 needle and an accurately fitting tuberculin syringe were used. No dressing was applied. In most cases only one injection was made, but in some of the early vaccinations two injections, each of 0.05 ml. of vaccine, were made, separated by a distance of about 2 cm. (see below).

The vaccines used (vaccines A and B) were supplied officially from two different sources (see table VI). On the recommendation of the Medical Research Council vaccine B was given in dose twice as large as that recommended by the suppliers.

Tuberculin testing after vaccination—Although it is generally accepted that tuberculin sensitivity develops about six weeks after the entry of the tubercle bacillus into the body, we delayed the subsequent tuberculin testing until between the eighth and tenth weeks after vaccination. This was to allow for possible individual variations in the development of sensitivity, and for variations in the virulence of the vaccines used. Subsequent experience proved that this was a wise procedure.

In determining tuberculin sensitivity it seemed reasonable—and it accords with current practice—to

TABLE VII—TUBERCULIN CONVERSION AFTER BCG VACCINATION

Vaccine	No vaccinated	No showing Mantoux conversion
A	92	92 (100%)
B	225	216 (96%)
Total	317	308 (97.2%)

accept the same standards after vaccination as before. No person was accepted as having undergone Mantoux conversion who did not show a reaction to 1 mg. or less of tuberculin.

Mantoux reaction after vaccination—At an early stage of this work Professor Cameron called our attention to the fact that the tuberculin reaction after vaccination differed in certain respects from the reaction caused by a natural infection. (A similar observation has been made by Prof. Benjamin Viel, of Santiago.)

In the Mantoux reaction which follows successful BCG vaccination the zone of initial erythema is often very large. The erythema fades very rapidly and when the reaction is read at forty-eight hours it may be seen only as a faint pink staining of the skin. The area of central swelling is of a livid plum colour, and although its margins can usually be fairly easily seen they are often difficult to define by palpation. Even severe reactions rarely show the central pallor or necrosis which are typical of severe tuberculin reactions following natural infection, and they are not associated with discomfort. We have not seen this feature described in detail, nor do we know its exact significance. The majority of the reactions conformed to the natural conversion type.

TABLE VIII—SIZE OF PAPULE AND TUBERCULIN ALLERGY AT ABOUT NINE WEEKS AFTER VACCINATION

Vaccine	No. of papules	No. in group	Papule av. and range of diam. (mm.)	Tuberculin sensitivity	
				Induration av. and range of diam. (mm.)	Amount of tuberculin (mg.)
A	2	58	11.8* (6-20)	11.4 (7-20)	0.1
A	1	31	7.2 (5-13)	10.4 (5-20)	0.1
B	1	12	5.6 (4-7)	9.7 (5-20)	0.1
B	1	105	5.6 (2-10)	13.8 (5-30)	1

* Average of the combined diameters of the two papules

Segregation—It was obviously impossible to segregate the group of nurses and students with whom this report is concerned. Both must work, and the risk of being misled through their contracting infection during the pre-allergic period had to be taken. Wallgren (1948) has admitted that the Scandinavian authorities regard segregation as more important for the good repute of BCG vaccination than for its actual prophylactic value. The danger to the vaccine's reputation of undetected infection—a risk which is always present unless segregation is absolute—is well illustrated in the outbreak of tuberculosis reported by Hyge (1947).

That BCG can be given safely to tuberculin positive subjects has been established by several investigators, and the same was shown in respect of the vole bacillus by Cameron and Purdie (1946). The danger of the so-called negative phase in the period of development of allergy has been investigated in animals by Bøe (1949).

Bøe injected BCG vaccine into guinea-pigs previously infected with tuberculosis. The injections were made at various stages in the development of the tuberculous disease, including the pre-allergic period. He was unable to show that the vaccine had any harmful effect when given in the pre-allergic period or while the tuberculous process was still moderate.

At the worst, failure to segregate merely nullifies the effect of the vaccine.

RESULTS OF VACCINATION

Mantoux conversion—At the present time the results of 317 vaccinations are known and the Mantoux conversion rate is shown in table VII. The 100% conversion rate with vaccine A is, of course, extremely satisfactory, and the over-all rate of 97.2% compares very favourably with the results reported by other workers. No immediate reactions of the type associated with previous infection were observed.

Table VIII sets out the size of the papule produced, and the extent of the tuberculin reaction after vaccination. We endeavoured to record the results uniformly, and only those results which were read at approximately the eighth week after vaccination are presented. Through circumstances beyond our control we were unable to test 111 individuals at this time. (It should be remembered when comparing these results that the dose of

TABLE IX—SIZE OF PAPULE AND CORRESPONDING CUTANEOUS SENSITIVITY TO TUBERCULIN AFTER VACCINATION

Vaccine	Diam. of papule (mm.)	No. in group	Amount of tuberculin (mg.)	Diam. of induration 5-9 mm. (Mantoux)		Diam. of induration 10-19 mm. (Mantoux)		Diam. of induration 20 mm. and over (Mantoux)	
				No.	% of no. in group	No.	% of no. in group	No.	% of no. in group
A	Less than 5	Nil	—	NR	—	Nil	—	Nil	—
	5-9	40	0.1	17	42.5	21	52.5	2	(5.0)
	10-19	46	0.1	12	26.1	32	69.6	2	(4.3)
B	Less than 5	37	1.0	24	64.8	8	21.6	5	13.6
	5-9	73	—	—	—	—	—	—	—

vaccine B contained twice the weight of organisms contained in the corresponding dose of vaccine-A)

Size of papule and extent of allergy—From table viii it will be seen that the average diameter of the papule produced by vaccine B was only 78% of that produced by vaccine A when one injection was made. When the dose of vaccine A was split into two equal portions of 0.05 ml., the average diameter of the combined papule sizes was 64% greater than that of the average papule produced by a single injection of 0.1 ml. of the same vaccine. Nevertheless, the average size of tuberculin reaction which developed was only 10% greater when the two injections were made. Heimbeck, of Oslo, has recommended the administration of the vaccine by splitting the dose into three intracutaneous injections, 1 in apart, but he does so from another point of view—to minimise the risk of abscesses (a risk which has not arisen in our experience). The giving of two (or three) intracutaneous injections has the disadvantage that a longer time is required to carry out the vaccination.

The size of the papule appears to be important from other points of view. Hertzberg (1949), reviewing the results of vaccination by the Oslo Health Service in the period 1932-46, concludes that the size of the local reaction to BCG influences the frequency of tuberculin conversion, the degree of cutaneous tuberculin sensitivity, the duration of allergy after vaccination, and the resistance to tuberculous disease. We have analysed our immediate results from the point of view of the frequency of conversion and the degree of cutaneous tuberculin sensitivity produced as estimated by the size of the tuberculin reaction.

It is noteworthy that the average diameter of the papules in the subjects in whom Mantoux conversion did not take place was 3.7 mm (2-5 mm). Hertzberg (1949) found that, among 1190 cases in which the local reaction had been recorded as 4 mm or less, the Mantoux conversion rate was 56.4% compared with 95-100% in cases where the local reaction exceeded 5 mm in diameter.

The relation between the size of papule and tuberculin sensitivity after vaccination is shown in table ix. Hertzberg concluded that there was a tendency for the local reaction (after BCG) to vary directly with the tuberculin sensitivity, but that in each grade of papule all grades of tuberculin sensitivity were found. The results shown in table ix are in keeping with Hertzberg's observations.

The papules produced by the two vaccines developed at different rates, and this table shows very clearly the smaller size of papule produced by vaccine B. At four weeks the papules produced by vaccine B were smaller, flatter, and showed less vesiculation and pustulation than the more active lesions produced by vaccine A. At eight weeks the papules produced by vaccine B were comparable in appearance with those seen at four weeks in persons vaccinated with vaccine A. At this time the latter papules were beginning to regress, but many still showed a vigorous reaction.

It is extremely difficult to compare the degree of tuberculin allergy produced by the two vaccines (see table viii). Preliminary testing indicated that cutaneous sensitivity was less with vaccine B than with vaccine A. On the assumption that 0.1 mg. of tuberculin would not discover all the conversions caused by vaccine B, a dose of 1 mg. was employed in the majority of this group.

In the small group (12) tested with 0.1 mg., and therefore comparable to those vaccinated with vaccine A, tuberculin allergy was slightly less. In the large group (105) tested with a tuberculin dilution ten times as strong, the average size of the reaction produced by vaccine B was 42% greater.

Development of allergy—It is usually agreed that tuberculin allergy develops between twenty-eight and

forty-two days after entry of the tubercle bacillus into the tissues. Yet of 94 students observed by us on the thirty-ninth day after vaccination, only 50 (53.2%) were Mantoux positive. A further test of the negative reactors on the seventieth day showed that the percentage of positive reactors in the whole group had risen to 95.8.

On account of the difficulty of inspecting the papules at short intervals it was impossible to observe accurately the rate at which they developed. The statements of 108 people who were questioned indicated that the papules appeared between five and fourteen days after vaccination, and in the majority of cases after the tenth to twelfth day.

COMPLICATIONS

No major complications were observed in the 317 vaccinations performed. We noted that sometimes, when the papules were succeeded by vesicles or pustules, these broke down and discharged, but in all these cases careful cleansing and the application of a dry dressing prevented sepsis, and there were no instances of persistent ulceration. In a few cases there was transient axillary discomfort, but in only 1 palpable glandular enlargement, in none did an abscess form. The vaccine in fact appeared to be innocuous.

SUMMARY

The organisation of a scheme for tuberculin testing and BCG vaccination of certain groups of students and hospital nurses in Edinburgh is described.

Of the 1350 nurses and 1302 students tuberculin tested, 17.4% in each group failed to react to 1 mg. of old tuberculin. The different rates of Mantoux conversion in nurses and in students are described.

Of the complete series of 2652 people, 462 failed to react to 1 mg. of old tuberculin. Of these, 429 (92.9%) were vaccinated with BCG intracutaneously, and the immediate results of 317 vaccinations are described. Two vaccines were used, one containing twice the weight of bacilli contained in the other.

Observations are recorded regarding the size of papule produced by vaccination and its relationship to subsequent allergy, as estimated by the size of the tuberculin reaction. The Mantoux reaction after successful vaccination differs in some respects from that which follows natural infection.

Vaccination has given rise to no serious complications.

This work was planned by Prof. Charles Cameron. We are indebted to him for criticism and help in preparing this paper, and to Dr. Ian Macgregor, of the Department of Health for Scotland, for his sustained interest in the work and for advice regarding formulation of some of the tables.

The Second Quarter

The following figures for England and Wales in the quarter ended June 30 have been reported by the Registrar-General¹

Births—The number registered was 181,784 representing a birth rate of 16.7 per 1000 total population. The rate in the corresponding quarter of 1949 was 17.6.

Stillbirths—These represented 22.5 per 1000 total births—0.4 less than in the second quarter of 1949.

Deaths—The death rate was 11.1 per 1000 total population compared with 11.0 in the corresponding quarter of 1949. The infant-mortality rate was 28 per 1000 related live births—the lowest recorded for any second quarter.

¹ The Registrar General's Quarterly Return for England and Wales: Births, Deaths, and Marriages, Infectious Diseases, Weather Survey of Sickness, Population Estimates for the Quarter ended June 30 1950. H.M. Stationery Office. Pp. 30, 15.

Poliomyelitis

In England and Wales notifications of poliomyelitis in the week ended Oct 28 were paralytic 182 (197), non-paralytic 71 (81), total 253 (278). The figures for the previous week are in parentheses. Notifications for the corresponding week in 1947 and 1949 totalled 280 and 307. Total uncorrected notifications for 1950 up to and including the week under review are 7543. The corresponding figures for 1947, 1948, and 1949 were 8022, 975 and 5259. A gradual reduction in notifications has now been maintained for several weeks.

Dr Newsholme's Retirement

Dr H P Newsholme, who in 1928 succeeded Sir John Robertson as medical officer of health for Birmingham, retired this year. Formerly Birmingham had an unenviable notoriety, but in Robertson's time it gained a first-class public health service which Dr Newsholme carried on with outstanding success. The school medical service had grown up independently of the public health service, and collaboration of these two services, without fusion, was the most notable achievement of Dr Newsholme's period of office.

Dr Newsholme's contributions to public health theory have been mainly philosophical, but his factual annual reports, with only necessary commentary, have a permanent place in public-health history. His last report—that for 1940—reveals a better state of health in the city than ever before. For the first year on record no child died of diphtheria. Pulmonary tuberculosis showed a slight increase in notification but a reduction in fatality. Maternal mortality was 0.39, or, including deaths from abortion, 0.49, per 1000 live and still births, and there were no deaths from sepsis. Infant mortality

gave a new low record of 31 per 1000 related live births. For years the Birmingham rate of infant mortality has been below that for England and Wales, this is a great tribute to local endeavour, for circumstances in this city are not favourable for a low rate.

REGISTRAR ESTABLISHMENTS

MINISTRY OF HEALTH STATEMENT

AN important announcement on the future establishment of senior registrars and registrars in England and Wales has been made by the Ministry of Health in a circular to hospital authorities. The circular (R.H.B. [50] 106) is summarised below.

1 It has from the outset been made clear that the senior registrar and registrar grades are regarded as training grades for potential consultants (or senior hospital medical or dental officers). It follows that the total number of appointments, particularly in the senior registrar grade, should be closely related to the likely number of openings.

2 It has also been indicated that training should be continued only for those who appear likely to benefit from it, and in particular that promotion from one grade to another should be competitive. The base of the training ladder should be the first year in the registrar grade—a grade which should normally be reached at least 2 years after qualification. The registrar should be reviewed at the end of the first year, and if satisfactory should normally proceed to a second year in this grade. Those wishing to proceed further should seek an appointment in open competition as senior registrar, the number of posts available being considerably less than the number of second year registrar posts. The senior registrar should also be reviewed at the end of the first and second years. At the end of the third year in a senior registrarship training should be complete, appointment for a fourth year should be very exceptional, and for the most part confined to certain specialties such as thoracic surgery, neurosurgery, and plastic surgery or to doctors who, having completed training as, for example, general physicians, wish to take up other specialties.

LIKELY NUMBER OF VACANCIES

3 For some years to come the number of appointments open to senior registrars who complete their training at

hospitals in England and Wales is unlikely to exceed 150 per annum. This includes, not only consultant and senior hospital medical or dental officer appointments to make good wastage through death or retirement, but also a proportion of additional posts and openings in other services and overseas as well as in hospitals in this country. Thus it appears that the number of training posts should not at present exceed the following: senior registrar, 600, registrar, 1100. The figure for registrars is a total for those in the first and second years of training, and that for senior registrars the total for those in the first, second, and third years.

4 At present the number in each of these two grades is upwards of 1400. "It is therefore essential to take steps to bring the number of training posts as quickly as possible into line with the numbers required."

5 The objectives should be

(a) To fix for each hospital regional area an establishment of training posts properly distributed between the different specialties and situated in hospitals with suitable facilities.

(b) To reduce the present numbers by (i) making appointments only up to the new establishment figures, and (ii) discontinuing appointments of senior registrars now in their third or subsequent years as the present year of appointment ends. (See also para 2 and para 9 (ii).)

(c) If necessary, to make alternative appointments for carrying out the work of the hospitals.

FIXING AN ESTABLISHMENT

6 Each regional board and the related board or boards of governors are asked to consider urgently together what training posts should be provided in the area within the maxima indicated below, and to submit their joint proposals by Jan 31, 1951. In preparing these proposals, the cooperation of the dean or director of postgraduate medical studies of the university should be sought. The proposals should indicate the number of senior registrar and registrar posts proposed for each specialty and the hospitals where these posts are to be held. The Minister will review these proposals as a whole, with particular reference to the distribution between specialties which can be satisfactorily determined only on a national basis.

7 It appears that the maximum total number of posts for each regional area (including teaching hospitals) should be

Region	Senior registrar (total for first second and third year)	Registrar (total for first and second year)
Newcastle	34	63
Leeds	36	65
Sheffield	42	76
East Anglia	18	32
North West Metropolitan	75	138
North East Metropolitan	48	86
South East Metropolitan	52	96
South West Metropolitan	83	151
Oxford	22	42
South Western	30	56
Wales	28	51
Birmingham	52	96
Manchester	52	96
Liverpool	28	52

The distribution between specialties will vary from region to region according to the training facilities, and the concentration of teaching resources in London will have to be taken into account

REDUCTION IN NUMBERS

8 In addition to fixing total establishments, an approximate distribution in each region of the total into numbers for each year of training must obviously be made, though this may vary slightly at different times. When the distribution of posts by specialty and hospital has been determined, it will be necessary to decide which of the existing first year registrars or first-year or second-year senior registrars can continue for a further year, and where new appointments in the first year of each grade can be made during the coming year. Regional proposals should therefore include a statement of the number of registrars and senior registrars by specialty in each year of training it is proposed to retain or recruit during the coming year.

9 When the establishment proposals have been approved by the Minister, these should be strictly adhered to. This means that

(i) The number of first-year registrars or senior registrars recruited during the year should be the number (within the approved total) which boards have decided is appropriate.

(ii) As the existing second year registrars and third year senior registrars reach the end of their personal year of appointment, their appointments should be terminated (except in the exceptional circumstances mentioned in paragraph 2), and first-year registrars and first-year and second-year senior registrars should be reviewed and reappointed for a further year's training only so far as this is possible within the approved total establishment.

10 From now on, boards should not renew the appointment of any second year registrar whose personal year of appointment ends, or of any third (or subsequent) year senior registrar except in the exceptional cases mentioned at the end of paragraph 2 or in accordance with the terms of paragraph 11 (a).

ALTERNATIVE APPOINTMENTS

11 Where a board is satisfied that the work of the hospital necessitates an alternative appointment in place of a senior registrar (but not otherwise), the following are among the steps that may be taken

(a) An existing senior registrar whose appointment as a trainee is not renewed may be offered an appointment for one year only as a temporary senior registrar at his present salary rate.

(b) Alternatively, boards may appoint as part time clinical assistant a suitably experienced general practitioner (normally one with a higher qualification and experience as a senior registrar or registrar). Remuneration will be announced later.

JUNIOR REGISTRARS

13 In future "junior registrars" will be known as "senior house officers," since this is not regarded as a trainee grade like that of registrar.

OTHER OPENINGS

An appendix draws attention to the openings outside the National Health Service. First, the three Armed Forces need 400 specialists, notably in the following specialties

anaesthetics, surgery, otology, radiology, psychiatry, pathology, dermatology, and venereology. In addition there are over 100 vacancies for general duty officers. Secondly, in the Colonial Service about 200 permanent or temporary posts are available. Thirdly, a number of overseas university and hospital appointments are vacant or will shortly be vacant principally in the Middle East and South East Asia, further information about posts in this third group may be had from the Technical and Scientific Register, York House Kingsway, London, W C 2.

Parliament

Vivisection and Cancer Research

ON the motion for the adjournment in the House of Commons on Oct 31, Mr PETER FREEMAN doubted whether experimentation on living animals was of real value in the search for a cure for cancer. In 1904 there were 8292 such experiments, and in 1919 they numbered 75,343. About two thirds of these were conducted without any anaesthetic for the animals concerned. About 80 % of the animals were allowed to recover and could be experimented upon again. The total number of experiments during the last half century had exceeded 1,300,000. Yet in 1900 deaths from cancer were 26,721, and last year they were 80,732. As possible causes which might be investigated, in preference to continued experiments on animals, he mentioned the stress of modern industrial life, the increased consumption of alcohol, tobacco, narcotics, animal and artificial foods, pasteurised milk, and patent medicines, and the modern craze for injections, serums, inoculations, and vaccinations. He had no doubt that there would be an overwhelming response to any request for men and women prepared to submit to reasonable experiment.

Dr CHARLES HILL declared that to assert that animal experimentation was futile was to fly in the face of facts. An enormous amount has been achieved, and at least one form of cancer was now curable as a result of animal experimentation. Dr Hill preferred to see animals rather than human beings used for attempts to induce cancerous growths.

Mr GEOFFREY DE FREITAS, under-secretary of State for the Home Department, in reply drew the attention of the House to the stringency of the safeguards under which these experiments were permitted. No animal experiment was permitted without a licence from the Home Secretary, and all were subject to inspection. A further special certificate was required when the animal lived after the experiment. The Home Office inspectors who advised the Home Secretary on the granting of these certificates did so on the basis of wide knowledge of the applicants' experience and of the suitability of the place of experiment. Most of the animals used were small rodents, chiefly mice, but occasionally rats or guinea-pigs. In the last two years there had been 24 experiments on cats and 28 on dogs. The most usual experiment was when a substance such as coal tar was applied to a small part of the skin of the mouse or a small amount was added to the animals' diet. Each application counted as one experiment, and the large figures quoted related to experiments and not to animals. Mr de Freitas pointed out that the death rate from cancer had remained fairly constant for the last thirty years and there had been a slight reduction each year in the mortality of women. The Medical Research Council held views on the value of animal experiments in cancer research which were directly contrary to those of Mr Freeman. In a recent report the council said

"There seems to be general agreement that most of the advances which have been made recently in our knowledge of the causation and treatment of various forms of cancer would have been impossible without experimental work on animals. Indeed there is no form of medical research which has been more dependent on animal work. Substances to which human beings may be exposed can be tested in animals for their tumour producing properties. This research has made possible the protection of many thousands of industrial workers."

A close control of these experiments was exercised by the Home Secretary and he asked the House to agree that this control was most carefully administered.

In England Now

A Running Commentary by Peripatetic Correspondents

THERE was consternation in our chest clinic the other morning as a result of the only passably useful piece of clinical research I have yet undertaken.

A trombone player in a world-famous orchestra had recently been discharged from the local sanatorium with a left artificial pneumothorax and he wanted to know whether he could safely give of his best work once more. Here was our chance. By careful staff work his formidable instrument was smuggled into the screening-room, whence in due course emerged the restrained trombone passages from the first movement of the Great C Major Symphony, though in our small clinic, noisy enough at best, this did not sound so restrained. Even after several bars, however, the expansion in his lung was less than half that produced by a quiet cough. We then transferred him to the refill-room to confirm this finding and obtained these eminently satisfactory readings on the manometer

Activity	Intrapleural pressure (cm of water)
Quiet respiration	-10 -7
Sustained conversation	-2
Trombone parts from	
Symphony in C Major—Schubert	-5 rising to -10
Prelude to act 3 of Lohengrin—Wagner	-10 to -12
Coda to Symphony No 2—Sibelius	-16 (maximum)
Quiet cough	-45 to -60
Loud cough	Too high to be read on our manometer

By this time the refill queue was getting restless and voices could be heard raised in anger. The trombonist explained that the average blowing time for a concert was 16 minutes and the average weekly total including rehearsals not more than 2½ hours. In view of the experimental findings I assured him that it would be perfectly safe to continue with his present work.

* * *

I was staying at the Bear Inn at Hungerford when I read in the papers about Princess Elizabeth's dress. When the Court went into mourning for King Gustav the Princess had no suitable black dress to wear at the Royal Command Film Performance that night. The Queen's dressmaker had his whole staff working on the job all day; they rushed the finished dress to Clarence House by 7 P.M., and everyone thought how nice she looked in it at 8 o'clock when the film show began. A triumph of modern organisation? I agree but there have been triumphs of the sort before. In the hall of the Bear Inn, for instance, hangs the story of how the Throckmorton Coat was made at Newbury in 1811. Sir John Throckmorton bet he could get a coat made from the raw materials in one day. Some chump took him on, though everyone knows that people who make such outlandish bets always win and Throckmorton produced two sheep. These were shorn at 5 A.M., the wool was washed and spun on the spot, sent to the local weavers to be dyed, dried, and woven and by 4 o'clock the cloth was ready for the local tailors, who removed their coats and finished Sir John's at a canter by 7.30 P.M. The main scenes in this drama are illustrated in comic-strip form above the document.

* * *

Women doctors, even if not so named, were part of our national life several hundred years ago, if we are to believe John Aubrey's *Lives*, written between 1689 and 1696, which have lately been republished. This discovery gave me a pleasant feeling of continuity with my maternal ancestresses who sprang from the same part of Wiltshire as Aubrey himself. Speaking of his grandfathers' days, not long before the dissolution of the monasteries, Aubrey says, 'The young mayds were brought up at the nunneries where they had examples of piety and humility and modesty and obedience to imitate and to practise. Here they learned needlework, the art of confectionery, surgery (anciently no apothecaries or surgeons—the gentlewomen did cure their poore

neighbours their hands are now too fine), physick, writing, drawing. This was a fine way of breeding young women, who are led more by example than precept." The curriculum is fuller now, though unfortunately the art of confectionery has been dropped, needlework is still useful, as a great surgeon remarked when he watched some of us women practise suturing the gut. Writing, by which Aubrey no doubt meant calligraphy, is badly neglected and many of us even boast that we write illegibly but drawing, or at any rate draughtsmanship, is still encouraged in the preclinical course. The modern teaching hospital is no nunnery, but there are plenty of examples of piety, humility, modesty and obedience to be found there if we look about, and a medical or nursing training is still a fine way of breeding young women.

* * *

O surgeons, lay the lancet lay the bistoury aside,
Unloose the gory gown and leave the mystic mask
untied

Forswear the silver catheter, your stitches all uncast,
Do not prescribe the cephalotribe, unhand the
cranioclast

The silence of your theatres be unwilling to profane—
I sing of the phlebotomist whose work was not in
vein

Now likewise ye physicians your patients have enough
Of drench and diuretic of purges *quantum suff*
Dispense with all your nostrums, break bottles, burn
the corks

Palpate not glands with furtive hands, sound not
your tuning forks.

Go, load em up with laudanum to still their cries of
pain

'Tis the phlebotomist I sing, whose life knew neither
snare nor sting

Except for one sad silly thing—his work was not in
vein

He sought the early writers, of whom his craft was
born

They cited him the pelican, they spake of unicorn,
They *thrice a goldene blood-soul'erc* to the bo'ine
of a pille

He fled the older workers' fold and looked up *Whit*
and *Brit*

Dissatisfied, he tried and tried, and wrought with
might and main

Until, at last you see him plough no more the gory
furrow now

Arma virumque Arms enow are finely bled, his
colleagues vow

I sing a man, you will allow, whose work is *not* in vain.

* * *

It is always comforting to find someone else with one's own complaint. I was wondering the other day, as I crossed the street in our market town, whether I was paranoiac. For ever motorist and cyclist seemed intent on running me down directly I stepped off the pavement. A few days later the *Times* published a letter from a man who shared my feelings exactly. He also had the reverse impression when driving (incipient megalomania)—that all pedestrians are suicidal nitwits. To me they appear more like sleep-walkers, gliding with glazed unseeing eyes in front of my bonnet when they should be at home in bed (where they soon will be if they are not more careful). But perhaps after all these ideas are not symptoms of a deranged mind.

* * *

The M.B. finals being depressingly near, I peripated for a week or so in South Wales. On the lower slopes of the Brecon Beacons I stopped to talk to an elderly hedger. He was soon telling me how he had TB in his youth and while waiting for a bed tried taking sheep dip (They call it non-poisonous, though there's poison in it) but the phlegm was still gaining on him, so he took half a sheep's fluke pill. That cured him. He hadn't told any doctors because they might put him in prison. I hope they won't.

7 It appears that the maximum total number of posts for each regional area (including teaching hospitals) should be

Region	Senior registrar (total for first, second, and third year)	Registrar (total for first and second year)
Newcastle	34	63
Leeds	36	65
Sheffield	42	76
East Anglia	18	32
North West Metropolitan	75	135
North East Metropolitan	48	86
South East Metropolitan	52	96
South West Metropolitan	83	151
Oxford	22	42
South Western	30	56
Wales	28	51
Birmingham	52	96
Manchester	52	96
Liverpool	28	52

The distribution between specialties will vary from region to region according to the training facilities, and the concentration of teaching resources in London will have to be taken into account

REDUCTION IN NUMBERS

8 In addition to fixing total establishments, an approximate distribution in each region of the total into numbers for each year of training must obviously be made, though this may vary slightly at different times. When the distribution of posts by specialty and hospital has been determined, it will be necessary to decide which of the existing first year registrars or first year or second year senior registrars can continue for a further year, and where new appointments in the first year of each grade can be made during the coming year. Regional proposals should therefore include a statement of the number of registrars and senior registrars by specialty in each year of training it is proposed to retain or recruit during the coming year.

9 When the establishment proposals have been approved by the Minister, these should be strictly adhered to. This means that

(i) The number of first-year registrars or senior registrars recruited during the year should be the number (within the approved total) which boards have decided is appropriate.

(ii) As the existing second year registrars and third year senior registrars reach the end of their personal year of appointment, their appointments should be terminated (except in the exceptional circumstances mentioned in paragraph 2), and first-year registrars and first-year and second year senior registrars should be reviewed and reappointed for a further year's training only so far as this is possible within the approved total establishment.

10 From now on, boards should not renew the appointment of any second year registrar whose personal year of appointment ends, or of any third (or subsequent) year senior registrar except in the exceptional cases mentioned at the end of paragraph 2 or in accordance with the terms of paragraph 11 (a).

ALTERNATIVE APPOINTMENTS

11 Where a board is satisfied that the work of the hospital necessitates an alternative appointment in place of a senior registrar (but not otherwise), the following are among the steps that may be taken

(a) An existing senior registrar whose appointment as a trainee is not renewed may be offered an appointment for one year only as a temporary senior registrar at his present salary rate.

(b) Alternatively boards may appoint as part time clinical assistant a suitably experienced general practitioner (normally one with a higher qualification and experience as a senior registrar or registrar). Remuneration will be announced later.

JUNIOR REGISTRARS

13 In future "junior registrars" will be known as "senior house officers," since this is not regarded as a trainee grade like that of registrar.

OTHER OPENINGS

An appendix draws attention to the openings outside the National Health Service. First the three Armed Forces need 400 specialists, notably in the following specialties

anaesthetics, surgery, otology, radiology, psychiatry, pathology, dermatology, and venereology. In addition there are over 100 vacancies for general duty officers. Secondly, in the Colonial Service about 200 permanent or temporary posts are available. Thirdly, a number of overseas university and hospital appointments are vacant or will shortly be vacant principally in the Middle East and South East Asia, further information about posts in this third group may be had from the Technical and Scientific Register, York House, Kingsway, London, W C 2.

Parliament

Vivisection and Cancer Research

ON the motion for the adjournment in the House of Commons on Oct 31, Mr PETER FREEMAN doubted whether experimentation on living animals was of real value in the search for a cure for cancer. In 1904 there were 8292 such experiments, and in 1949 they numbered 75,343. About two thirds of these were conducted without any anaesthetic for the animals concerned. About 80% of the animals were allowed to recover and could be experimented upon again. The total number of experiments during the last half century had exceeded 1,300,000. Yet in 1900 deaths from cancer were 20,721, and last year they were 80,792. As possible causes which might be investigated, in preference to continued experiments on animals, he mentioned the stress of modern industrial life, the increased consumption of alcohol, tobacco, narcotics, animal and artificial foods, pasteurized milk, and patent medicines, and the modern craze for injections, serums, inoculations, and vaccinations. He had no doubt that there would be an overwhelming response to any request for men and women prepared to submit to reasonable experiment.

Dr CHARLES HILL declared that to assert that animal experimentation was futile was to fly in the face of facts. An enormous amount has been achieved, and at least one form of cancer was now curable as a result of animal experimentation. Dr Hill preferred to see animals rather than human beings used for attempts to induce cancerous growths.

Mr GEOFFREY DE FREITAS, under-secretary of State for the Home Department, in reply drew the attention of the House to the stringency of the safeguards under which these experiments were permitted. No animal experiment was permitted without a licence from the Home Secretary, and all were subject to inspection. A further special certificate was required when the animal lived after the experiment. The Home Office inspectors who advised the Home Secretary on the granting of these certificates did so on the basis of wide knowledge of the applicants' experience and of the suitability of the place of experiment. Most of the animals used were small rodents chiefly mice, but occasionally rats or guinea-pigs. In the last two years there had been 24 experiments on cats and 28 on dogs. The most usual experiment was when a substance such as coal tar was applied to a small part of the skin of the mouse or a small amount was added to the animal's diet. Each application counted as one experiment, and the large figures quoted related to experiments and not to animals. Mr de Freitas pointed out that the death rate from cancer had remained fairly constant for the last thirty years and there had been a slight reduction each year in the mortality of women. The Medical Research Council held views on the value of animal experiments in cancer research which were directly contrary to those of Mr Freeman. In a recent report the council said

'There seems to be general agreement that most of the advances which have been made recently in our knowledge of the causation and treatment of various forms of cancer would have been impossible without experimental work on animals. Indeed there is no form of medical research which has been more dependent on animal work. Substances to which human beings may be exposed can be tested in animals for their tumour producing properties. This research has made possible the protection of many thousands of industrial workers.

A close control of these experiments was exercised by the Home Secretary and he asked the House to agree that this control was most carefully administered.

The size and administrative structure of the whole or parts of the organisation should be such as to engage the loyalty of all those concerned in the enterprise

Opportunity should be given for the development of individuality in the parts of the organisation

Power in the organisation should not be given to those whose loyalty is centred in a conflicting organisation

The conditions should provide for personal contacts between the workers in the organisation at different levels. Medical administrators should not be allowed to lose the medical touch by remoteness from people as patients

The conditions should encourage the exercise of the better ethical qualities. Interest in making money or careerism should not be rewarded and stimulated to the detriment of interest in medicine and humanism.

In making appointments to the staff, qualities other than mere technical qualification should be given full consideration

There should be general agreement on the basic aims of the organisation so that actual direction will be reduced to a minimum and the recurring problem will be the definition of the situation

Self-criticism in members of the organisation should be stimulated by the knowledge that their behaviour is manifest to colleagues who are competent to judge it

Walton Hospital,
Liverpool.

HENRY H MACWILLIAM

LIQUOR AMNII IN HÆMOLYTIC DISEASE OF THE NEWBORN

SIR,—Mr Bevis's interesting observation (Sept 30), that in hæmolytic disease of the newborn the liquor amni may contain iron, prompts us to record some investigations into the significance of coloured liquor amni, recently made with the help of our obstetric colleagues at this hospital.

Starting from the fact that in hæmolytic disease the liquor is often coloured yellow, we have tested the liquor in six cases of this disease, with the following results. In two cases liquor, taken 1-3 days before parturition at 36 and 40 weeks, was colourless and bilirubin free, in both cases the infant proved not severely affected. In three cases, tested at 34-35 weeks, the liquor was yellow with a trace, 0.9 and 1.2 mg per 100 ml. of bilirubin, all three proved to be cases of hydrops fetalis with death at or shortly after birth. In the sixth case liquor was taken at 41 weeks, 2 days after intra uterine death had taken place, this liquor was dark green and had a bilirubin content of 8 mg per 100 ml. From these few figures it appears that coloured bilirubin-containing liquor tends to be associated with severe forms of the disease.

However, coloured liquor is sometimes found in normals. The liquor from fifty nine subjects not involving hæmolytic disease was tested, and in six the colour was yellow or green. In three of these six the bilirubin content was between 0.5 and 1.2 mg per ml, in the other three the pigment unexpectedly failed to react with van den Bergh reagents.

In order to discover whether meconium staining could account for the coloration of liquors, we made up suspensions of meconium in a colourless sample of liquor. A 1.25% suspension of meconium gave a liquid with a green tint comparable to those seen clinically, and proved to have a bilirubin content of 1.6 mg per 100 ml—i.e., of the same order as that found in our clinical material. It seems that meconium staining is the probable cause of the coloured liquor occasionally seen in normals. It is surprising that some of these coloured liquors have failed to react with van den Bergh reagents, since biliverdin is said to be the main pigment in meconium and to give a similar diazo reaction to bilirubin.

It may well be that the bilirubin which we have found in the liquor of severe cases of hæmolytic disease also comes from meconium, and that where hæmolytic is active in the fetus, with bile pigments present in high concentration, the liquor is coloured.

coloured by small amounts of bilirubin which would ordinarily be insufficient to do so. Possibly the iron which Mr Bevis has found in the liquor in hæmolytic disease may also have come from the meconium.

We had originally hoped that the bilirubin content of liquor might provide some guide to the degree of involvement of the fetus by hæmolytic disease. But from Mr Bevis's work it seems that the iron content is more likely to prove of use in this sense.

A C T H AND FATTY LIVER IN RABBITS

SIR,—In the course of investigations on the possible release of progestational material from the adrenals of A C T H treated rabbits, well-marked fatty infiltration of the liver was observed after administration of relatively small amounts of this substance. In most cases the mobilisation of fat to the liver was accompanied by visible lipæmia.

The animals were ovariectomised one month before the start of the experiments and were primed with 25 µg of oestradiol benzoate on each of 6 consecutive days. The A C T H preparation used was an electrophoretically purified homogeneous A C T H-protein,* administered on 5 subsequent days. Liver fat was estimated histologically as sudanophil lipid, by the grading system of Hartman et al.¹

The results are summarised in table I. When the experiments were repeated in normal female rabbits, the results, shown in table II, were essentially the same.

TABLE I—FATTY INFILTRATION OF THE LIVER OF OVARECTOMISED RABBITS PRIMED WITH OESTRADIOL BENZOATE, AFTER ADMINISTRATION OF PURE A C T H

Rabbit no	Weight (kg)	Daily dose A C T H (mg per kg)	Length of treatment (days)	Total dose A C T H (mg)	Fatty infiltration†
1	4.0				0
2	3.8				0
3	3.5				0
4	3.5	0.8	5	14.0	+++ +
5	3.4		5	14.0	+++ +
6	3.0	0.65	1	2.0	+++ +
7	3.2		2	4.0	+++ +
8	3.3		5	10.0	+++ +
9	4.0	0.25	5	5.0	+++ +
10	4.1		5	5.0	+

TABLE II—FATTY INFILTRATION OF THE LIVER OF NORMAL FEMALE RABBITS AFTER ADMINISTRATION OF PURE A C T H

Rabbit no	Weight (kg)	Daily dose A C T H (mg per kg)	Length of treatment (days)	Total dose (mg)	Fatty infiltration†
11	3.5				0
12	2.0				0
13	2.5	1.2	5	15.0	+++ +
14	3.5	0.8	5	14.0	+++ +
15	3.1	0.65	5	10.0	+++ +
16	3.0		5	10.0	+++ +
17	4.1	0.25	5	5.0	+++ +
18	3.7		5	5.0	++

† According to the grading system of Hartman et al.¹

These findings confirm the experiments on rats by Baker et al.² and they agree with the results of Levin,³ obtained in mice. It is interesting that recently Kobernick and More⁴ reported marked lipæmia in rabbits treated with 'Cortisone'.

* Our thanks are due to Dr C H. Li who kindly supplied this preparation.

Letters to the Editor

DISTINCTION AWARDS

SIR,—The letter from "A B C" in your last issue prompts me to write and explain how those who have a similar dislike for and reluctance to accept Distinction Awards can give the maximum benefit to any charitable object of their choice. If they give a subscription out of their taxed income without covenanting to continue it for seven years that nett amount is the total received by the "charity", but if they enter into a covenant to give the same amount each year for seven years or during their lifetime (whichever period is the shorter) the income tax can be recovered by the charity in whose favour the covenant is drawn. The benefit is thereby nearly doubled.

I hope that many who may follow the example of "A B C" will feel inclined to support the Royal Medical Benevolent Fund. Others may have other objects foremost in their minds—such as the Royal Medical Foundation of Epsom College, their own schools or universities, the restoration fund of the Royal College of Surgeons, the extension of the Royal Society of Medicine—or they may wish to divide their gifts between two or more objects. The officers of any of these institutions will be anxious to provide prospective donors with the appropriate forms of covenant.

WEBB JOHNSON

DANGER OF HEXAMETHONIUM IODIDE

SIR,—During the last eight months while using methonium halides, and hexamethonium iodide in particular, on more than one occasion we have observed a marked fall in systolic blood-pressure in robust men. These patients initially had a normal blood pressure, and the state of circulatory collapse which resulted was an incidental finding to our clinical researches.

We feel that the dangers accompanying the use of these substances in domiciliary practice should be stressed, and also that insufficient publicity has been given to the use of ephedrine hydrochloride as an antidote. We have confirmed the finding of others, that ephedrine hydrochloride administered intramuscularly in a dose of 1-2 grams will rapidly raise the systolic pressure again.

MASS MINIATURE RADIOGRAPHY

SIR,—Last August I was visited by a doctor from Victoria, Australia. In his opinion, mass miniature radiography would be much more successful in this country if the volunteers were not made to undress for the examination. I was impressed with the idea and proceeded cautiously to ascertain the correct technique for X raying volunteers without their undressing fully.

Our results up till now are very striking. The miniature X-ray films are of a very high quality and are certainly not inferior to those taken in the ordinary way. Women are asked to remove overcoats and coats, necklaces, and metal objects or ornaments, such as brooches, from their blouses. Men remove their jackets and waistcoats, and slip their braces down to the waist. In the case of women, the X ray films show small metallic buckles and fasteners or clips associated with brassieres, but as a rule these are readily recognised as such and are situated in places where they do not interfere with the reading of the miniature film.

The great advantage is that men and women can be X-rayed at the same sessions. This is most beneficial,

especially at public or "open" sessions, and at contact sessions, when whole families can be X rayed, one after another. At the moment all male members are invited to attend on one day, and the female members on another. When the whole family can attend at the same time, the response is likely to be very much better. Moreover, much time is saved.

Chest Radiography Centre,
Nottingham

Medical Director

HOSPITAL ADMINISTRATION

SIR,—I think your correspondent (Sept 30, p 450) rather underrates the amount of thought that has been given to administration since the days of Florence Nightingale.

Hospital administration is merely a part of health service administration, which is itself a special field of human relations. Principles may be selected at various levels. Those which your correspondent has chosen apply purely at hospital level, but I think that consideration of more general principles might be beneficial to the service.

In his Linacre lecture Dr F M R Walshe¹ quoted from R J 'Collingwood's book *The Idea of Nature* as follows:

"A man who has never reflected upon the principles of his work has not achieved a grown up man's attitude to it. A man who has never enjoyed a certain type of experience cannot reflect upon it."

All doctors in this country have had experience of voluntary teaching hospitals, their obligations and their methods of administration, but only a limited number have had, in addition, experience of local authority hospitals. The tendency of the Ministry of Health to follow the voluntary hospital pattern may possibly be due to the fact that those whose reflections have influenced the Ministry have had only limited experience.

I suggest as principles the following from my own observations:

The purpose, scope, and range of the activity should be clearly enunciated.

The duties and obligations of voluntary hospitals were different from those of local authority hospitals, and the functions of hospitals in a complete co-ordinated health service are different from either.

The organisation should be for human beings in their complete social environment.

People should be regarded as free individuals and not as abstractions, such as masses of clinical material.

Primary aims should be kept clearly in view, and secondary aims such as, for example, medical education should not be allowed to take first place.

The administration should be for the whole of the activity, and the tendency of specialists to organise for parts of people or for narrow sections of the population should be corrected and checked or supplemented.

The limitations of technicians—clerical, financial, architectural, engineering, medical, and so on—should be admitted and the interests of the consumer for whom the organisation primarily exists be safeguarded.

Responsibility should be clearly defined.

Power should not be given without responsibility.

Power and responsibility should be placed close together and in proportion to each other. They should be placed close to the point of activity.

Power should not be remote and anonymous. The sense of responsibility should not be weakened by the evasions possible in committee control or by diffusion over too wide a field.

The consequences of decisions should be demonstrated to the person making the decisions.

Duties and responsibilities should be placed in appropriate hands—medical administration should be vested in doctors, clerical in secretaries, financial in accountants, and so forth.

Obituary

ERNEST GORDON GRAHAM-LITTLE

KT, B A CAPETOWN, M D LOND, F R C P

Sir Ernest Graham-Little had a long record of distinguished public service as member of Parliament, university senator, and consulting dermatologist.

He was born, in 1867, in Bengal, where his father, Michael Little, J.P., held a position in the Civil Service. His mother was a South African and he was educated at the South African College, Cape Town. A gold medalist and a Porter scholar, he took his B.A. in 1887 at Cape University before he came to this country to study medicine at Guy's Hospital and St George's Hospital. He qualified in 1892, and he graduated M.B. with honours in 1893. After postgraduate study in Dublin and Paris

he took his M.D. the following year and the membership of the Royal College of Physicians in 1895. He quickly won recognition as a dermatologist, and he was already on the staff of the East London Hospital for Children at Shadwell when he succeeded Sir Malcolm Morris as physician in charge of the skin department at St Mary's in 1902. He also held a university lectureship there, and he was thus a teacher in dermatology in the vintage period of Galloway, Burnett, Sequerra, Whitfield, and Adamson. In 1906 he was elected F.R.C.P.

He maintained his interest in pathology and he

carried over to his specialty his skill with the microscope. His contacts with other dermatologists were wide. At one time president of the dermatological section of the Royal Society of Medicine, and editor of the section of skin diseases in the *Medical Annual*, he was also in touch with the dermatological societies of over a dozen foreign countries, and he was honorary president of the ninth international dermatological congress held in Budapest in 1935.

But this side of his career was gradually overshadowed by his work for the University of London and as a member of Parliament. For over 40 years he represented the medical graduates of London University in the senate, where he stoutly resisted the attempt to fasten on the university an official co-operation in its final M.B., B.S. examination with the Conjoint Board. At a time when women had limited opportunities for clinical education in London he secured the recognition of the West London Hospital as an institution where they might be admitted as external students. But his services to the university did not rest with his membership of the senate. He was also chairman of the external council and president of the University of London Graduates' Association, and in 1924 he was elected to Parliament as university representative.

This seat he continued to hold until the university franchise was discontinued. He sat, appropriately enough as an Independent, for he was a convinced and often effective controversialist. In the House of Commons he was an alert guardian of the interests of the medical profession, and he consistently resisted any concession to unqualified medical practice. He was a member of the parliamentary committees which sat on the Road Traffic Act, the Marriage Act, the Factories Act and the earlier Criminal Justice Bill which was one of the casualties of the war. His criticisms of the National Health Service were sharp, but they were founded on principles sincerely held. A colleague writes: "Graham-Little had a flair for the political life, which he developed both in the University of London and in Parliament. He had a genius for organising successful elections and he was a pamphleteer of persuasive and masterly skillfulness."

(Press Portrait Bureau)

To these main activities he added a large range of subsidiary interests. He was a member of the council of the British Chess Federation, the Footpaths Preservation Society, and the Society of Individualists, while wholemeal bread, the British Empire, and backward races were other subjects on which he contributed pungent letters to the editors of the daily press, the medical weeklies, and erudite periodicals.

He married Miss Helen Kendall, who survives him. Together they shared the tragic loss of their only daughter in a bathing accident, and of their only son on active service with the R.A.F.V.R. Sir Ernest died on Oct 6 at his house at Epsom, where he had lived since his Wimpole Street house was destroyed by bombing.

DOUGLAS STUART STEVENSON

M.B.E., M.B. GLASG., F.R.F.P.S.

Dr Douglas Stevenson, physician to the Western Infirmary, Glasgow, died on Oct 21. He was born and educated in Glasgow, and his mother was a sister of J.H. Teacher, who held the chair of pathology in the university. During the 1914-18 war he served with small naval patrols till in 1917 he returned to graduate. He at once joined the R.A.M.C., and later the medical branch of the new Air Arm. For his services he was appointed M.B.E. and awarded the Belgian *croix de guerre*. He thus held commissions successively in all three Services, and in 1942, though no longer a young man, he characteristically abandoned private practice to act as consulting physician to Scottish command. He took a keen interest in ex-Servicemen and their problems.

"He graduated," writes J. McN., "into pure consulting medicine, like many of his generation (but this is ended now), as a family physician. He was in fact for years the trusted physician and adviser of many families round about Glasgow, who will not fail to remember his skill, courtesy, and friendship. This initial phase made Stevenson, when he obtained his wards at the Western Infirmary, an ideal practising consultant physician. He was never greatly interested in research, but rather in the care of his patients and also of the situation, domestic and otherwise, created by their illness. Thus Stevenson was a splendid teacher of medical students intending to become general practitioners, and such men are becoming rarer every day." Dr Stevenson was an honorary lecturer in clinical medicine at the university.

One of his former clinical assistants writes: "Stevenson was a very energetic practitioner-consultant with a remarkable flair for grasping the essentials of a clinical problem. His teaching was lively and convincing and often illustrated from his experience in general practice. As a consultant he developed a special interest in clinical haematology. He had a passionate love of tradition, and those who knew him well could not fail to be impressed by his strong sense of duty. Douglas loved the open air, and his remarkable memory—visual and auditory—enabled him to describe long excursions into the lonely places of the Highlands. As a young man he played rugger, and he was a skilful yachtsman and a good shot."

GEORGE ALLISON ALLAN

M.D. GLASG., F.R.C.P., F.R.F.P.S.

As a young man Dr Allan abandoned a business career to study medicine. Graduating M.B. with honours in 1905, he took the Brunton prize as the most distinguished graduate of his year. After 18 busy years in general practice in Glasgow, he turned his attention to consulting medicine with a special interest in cardiology. Even at this stage of his life he retained his unusual intellectual flexibility, for he was awarded the Bella Houston gold medal for his M.D. thesis in 1924, nearly 20 years after taking his M.B.

Allan's principal appointment was that of visiting physician to the Western Infirmary, where he worked under a succession of distinguished clinicians, but his services were constantly in demand at half a dozen smaller institutions beyond the city. He was a shrewd diagnostician and a most understanding doctor, and these qualities accounted for the rapid growth of his consulting practice in the West of Scotland. As a physician in charge of wards he enjoyed a high reputation both as a chief and as a painstaking teacher, and he took

It is plausible to assume—as Archer⁵ pointed out—that the same prompt mobilisation of fat to the liver may take place in man. The promptness of the fatty infiltration of the liver following the administration of relatively small amounts of pure ACTH seems to warrant a careful search for similar effects in human beings.

"PER CAPITA"

SIR,—I am grieved to find that you too (Nov 4, p 498) appear to be among those who have fallen before the Medusa of the National Health Service, and that the Latin instilled into you as a schoolboy appears to have evaporated. I had hoped that THE LANCET might remain immune from this proletarian disease.

London W 1

DOUGLAS ROBERTSON

*** Our immunity to this particular error is now restored to a high level.—Ed. L.

LEPTOSPIRAL MENINGITIS

SIR,—The article by Dr Geffen and Dr Tinker (Aug 5), and Dr Calnan's letter (Sept 30), each referring to a single case of leptospiral meningitis in 1949 and 1950, suggested to us that a further note of our experience might be of value.

The routine tests carried out on sera from all cases of aseptic meningitis, abortive poliomyelitis, or ? virus meningitis sent for investigation to the Virus Reference Laboratory, consist in complement fixation tests for the viruses of lymphocytic choriomeningitis and mumps and agglutination tests for leptospira. The Paul Bunnell test was done for several years without positive results and is no longer carried out unless there is some other indication. Of 130 patients studied in 1949, 10 were found by one of us (J. C. B.) to have serological evidence of leptospirosis (8 *L. canicola* and 2 *L. icterohæmorrhagiae*), 5 cases were recent infections with the virus of lymphocytic choriomeningitis, and 2 were mumps meningitis (following about a week after fleeting parotitis). These results were recently presented (F. O. MacC.) at the 6th International Congress of Paediatrics. Of 67 similar cases from Jan 1 to June 30, 1950, 3 have been found to be leptospirosis (2 *L. canicola* and 1 *L. icterohæmorrhagiae*).

J. C. BROOM

MEIGS'S SYNDROME

SIR,—Dr Macpherson suggests (Sept 30) that ascites and hydrothorax in Meigs's syndrome is caused by a similar mechanism to that in cirrhosis of the liver. I believe that in cirrhosis and other hepatic abnormalities these phenomena may be due to the abnormal liver compressing the inferior vena cava.

We have studied two cases which appear to substantiate this theory.

In one case, where there was cirrhosis with a large liver, the venal caval obstruction developed gradually and after two years was complete, finally producing grossly abnormal collateral circulation. That the site of obstruction was not at the opening of the diaphragm or in the adjoining pericardium was proved by exploratory operation.

In the second case there was a large heavy liver, due to fatty degeneration and when first seen the patient had for three months been constantly orthopneic, she had gross oedema of the lower abdomen and legs, ascites, and right hydrothorax. When she was made to lie flat in bed all oedema disappeared within a few weeks, and the body weight dropped from over 190 lb to 130 lb, the hydrothorax

diminished more gradually. During the next two months oedema could be produced by getting her to sit upright, day and night, for five days. After six months' treatment with a high protein diet and choline the liver returned to normal size, and no oedema, ascites, or hydrothorax reappeared even while she was walking about, although her serum proteins remained at the initial low level.

The concept of venal caval obstruction by the liver is not entirely new. Bull¹ has published convincing evidence that in lordotic people it explains the existence of orthostatic albuminuria. A large heavy liver is apt to rotate excessively when the patient stands, and it is remarkable that clinical disorder from increased venal caval pressure is not more common. The caudate lobe, as seen at routine autopsies, is a very variable structure and sometimes appears to compress the vena cava when moderate traction is applied to the vena cava. The predisposition to hydrothorax can be explained by the enormous engorgement of the azygos vein produced by venal caval obstruction, when this is combined with altered serum proteins there is reason to expect the appearance of hydrothorax.

Dr Macpherson's post mortem findings in cirrhosis appear to accord with the theory of venous back pressure. The evidence of low grade infection may be just a terminal complication in a patient with a failing liver. A more detailed analysis of his findings would help to elucidate the problem.

I have never investigated the venous return in Meigs's syndrome and I fail to see how the presence of a small ovarian tumour could influence the above mechanism. In most reported cases, however, there has been a fairly large pelvic tumour, and possibly there may be traction on the lower end of the vena cava. Borg² reported a very dilated azygos vein at autopsy in a case of Meigs's syndrome, while Gardner and Lloyd Hart³ have collected other evidence that the mechanical obstruction of venous return in the abdomen was the most likely explanation.

St Vincent's Hospital,
Dublin

D. K. O'DONOVAN

THE N H S THROUGH AMERICAN EYES

SIR,—I have noted with interest your very fair comment last week, but I feel that your comparison of annual expenditure on medical care in the U.S.A. and this country may be somewhat misleading. By converting American expenditure into pounds at the present rate of exchange, your editorial suggests that nearly three times as much is spent per person on the medical services in the States as over here. The rate of exchange, however, is not a suitable basis for comparison and conversion. The cost per person of the medical services in each country should be measured by the "sacrifices" which the individual has to make to secure them. If an American typist earns \$45 a week she will have to work for 7-8 days to provide the \$70 which represents the annual average cost of medical care in the U.S.A. Her British counterpart earning £5 15s a week will have to work for exactly the same period to provide the £9 which represents the annual average cost of medical care here.

If wages and prices are studied on this economic basis, the annual cost of medical care per person does not differ significantly in the two countries.

Pinner Middlesex.

H. W. TOMSKI

*** Comparisons of this kind are misleading whatever rate of exchange is chosen. We were, therefore, careful to mention the more instructive statement that medical care absorbs in the U.S.A. 4.9% of the national income and in Britain 4%. This seems to refute American suggestions that we are devoting an extravagant proportion of our resources to health.—Ed. L.

Notes and News

DISTRIBUTION OF GENERAL PRACTITIONERS

THE suggestions by the Medical Practices Committee¹ for a more even distribution of general practitioners have been taken to heart by the Ministry of Health. In accordance with these proposals, executive councils are being set up to consider, and report by Jan. 31, whether action should be taken to encourage more practitioners to settle in under-doctored areas enumerated by the committee in Schedule 1 and in other—particularly rural—areas named in Schedule 2 where the service may be inadequate. The duty of executive councils, says the Ministry, is, in association with medical committees, to stimulate the redistribution of practitioners in accordance with the public's needs, and this is to be achieved by (1) encouraging practitioners to take partners (or assistants preferably with a view to partnership), or, failing this, (2) advertising the need for further practitioners, who would qualify normally for a basic salary possibly for an inducement payment. The councils are advised, moreover, that inducement payments may be made by the Ministry "in order to produce an increase in the number of doctors not only in sparsely populated areas but also in those other areas which have hitherto proved relatively unattractive to doctors, such as highly industrialised areas." Finally, where more doctors are needed and houses are scarce, councils are enjoined to enlist the help of the local planning authority.

The following amendments have been made to the Medical Practices Committee's classification of executive-council areas: described in our issue of Aug. 5 (p. 229). Schedule 1 lists the names of parts where more doctors are needed, and Schedule 2 lists the "closed areas."

Schedule 1

DELETIONS

Wiltshire—Ripley T.D.
Wiltshire and Rutland—Milton Mowbray (excluding Wiltshire)

Schedule 2

ADDITIONS

Wiltshire—Malpas
Wiltshire and Rutland—Poverest ward of Orpington T.D. (area adjacent to St. Paul's Cray)
Wiltshire (East)—Ancaster Caythorpe Navenby
Wiltshire (East)—Wickham Market (Deben R.D.)

DELETIONS

Wiltshire and Rutland—Brixham Torrington.
Wiltshire (Holland)—Gedney Hill (East Elloe R.D.)

CORRECTIONS

Wiltshire and Rutland—St. Mary's Cray should read St. Mary Cray.
Wiltshire (East)—Presingfield (Hartismere R.D.) should read Singfield (Hartismere R.D.)

MANCHESTER MEDICAL SOCIETY

AT the inaugural meeting, on Oct. 4,³ Mr. Wilson Hey, the president, traced the origins of the new Manchester Medical Society from the time of the Literary and Philosophical Society in 1781. This was almost entirely a medical society for some thirty years during which time the presidents and most of the vice-presidents were medical men. In 1834 the original Manchester Medical Society was formed, with 91 members; today there were approximately 1000. Its transactions were printed 107 years ago in the *Provincial Medical Journal*—now the *British Medical Journal*. Later it was continued in the *Medical Chronicle* which appeared between 1884 and 1916. Eventually the society moved to Owens College—now the Victoria University of Manchester. Its library incorporated with the university departmental libraries was the largest in the country outside London, it had almost 100,000 books. In 1929 it was given to the university and now members had the privilege of using the university libraries. In 1879 the microscopical section of the society was formed, but since it was apparent that the microscope dealt with only a minute part of pathology, an independent Pathological Society was formed six years later, and it had flourished ever since. Mr. Wilson Hey referred to the formation of the old Clinical Society which was founded in 1925, the Surgical Society founded in 1922, and the Society of Anaesthetists, the Obstetrical Society, the Ophthalmological Society, the Otorhinolaryngological Society, the Odontological Section, and

numerous others that had developed from these or had been founded by Manchester men. In all, 22 medical societies had been thus originated.

Amalgamation, which had first been suggested in December, 1918, but for various reasons had been postponed, was now completed. The new society, centred on the university, had followed the pattern of the Royal Society of Medicine, each society becoming a section. Each section had its president, who was a vice-president of the society, and an honorary secretary. There was only one honorary treasurer, and for the first time there was a whole time paid secretary. Monthly diaries were being issued, and soon the society would have its *Proceedings and Transactions*.

The general practitioner was the chief thought of the council, which had in mind the formation of a special general practitioners section. The percentage of practitioner members of the various societies had diminished as a result of the Acts of Parliament which came into force in 1911 and 1948, these had converted the practitioner into a "form filling, regulation bound doctor." This decline had been assisted by two wars and to some extent by the intermittent post-graduate classes. The societies and sections had always been postgraduate classes, and now that the general practitioner was a public servant his fees and expenses ought to be paid by the Ministry, because such classes made him a greater asset to the patient and to the nation.

INTERNATIONAL DENTAL JOURNAL

THE first issue of this journal¹ realises a project postponed from before the war. The president of the International Dental Federation (F. L. Nord, of Amsterdam) describes in a foreword the difficulties that have had to be overcome, and pays a warm tribute to the group of British dentists, led by Prof. H. H. Stones, who have undertaken the editorial work. It was hoped at one time that the journal would be written in four languages, but present-day conditions make this impossible and all the articles now appear in English. The contributors include Prof. Harry E. Frisbie, of California University, who discusses the aetiology of dental caries with particular reference to the proteolytic theories, Mr. Bryan Wood, editor of the *British Dental Journal*, who surveys British dental services, and Prof. W. J. Tuckfield, who deals with impression techniques in full denture prosthesis.

University of Oxford

The degree of D.M. has been conferred on N. B. Mivart and the degree of B.M. on Patience Proby.

University of Cambridge

The following degrees have been conferred:

M.A.—D. M. T. Gairdner
M.D.—G. P. Baker, Mary Farquharson, J. A. Harrington, Alan Lyell, P. E. Perceval.
M.B. B.Chir.—*Elizabeth M. D. Craig, *George Holden, *J. F. Hort, *J. D. Jackson, *J. F. Lee, *R. P. Ross, *S. E. Sebag Montefiore.

* By proxy.

University of London

At recent examinations the following were successful:

D.C.P.—Dineshananda Balidya, L. A. Blackmore, V. St. E. D. Abnera, Phyllis Dagnall, J. L. Holme, Akhtar Husain, O. G. Jones, Andre Kertész, Felix Kurrein, Max Millard, Gopinath Prasad, Mohanty Hari Prasad, W. D. Ratnare, Rosemary J. S. Sichel, Mohan Lal Sur, Andrew Tay, Louis Vogel (academic postgraduate diploma), G. T. Barnes, K. S. Daber, Narindra Prasad Jain, J. K. F. Mason, J. B. Neal (external diploma).

University of Durham

Dr. W. B. A. Smyth has passed the examination for the diploma in public health.

University of Liverpool

Sir James Learmonth will give the William Mitchell Banks lecture on Thursday, Dec. 7, at 5 P.M., in the arts theatre of the university. His subject is to be Portal Hypertension.

University of Manchester

Dr. Kathleen V. Lodge has been appointed demonstrator in pathology.

University of Glasgow

On Nov. 4 the degree of M.D. was conferred on J. T. Aitken.

a keen personal interest in the welfare of his assistants and his students. An exacting professional life did not deter him from undertaking clinical research, and he wrote upwards of 50 papers—many of them on cardiology. He was co-editor of the *Glasgow Medical Journal*, a member of the Cardiac Society, and a councillor of the Association of Physicians. Since 1919 he had been a fellow of the Royal Faculty of Physicians and Surgeons of Glasgow, and in 1932 he was elected to the fellowship of the Royal College of Physicians of London.

A colleague writes: "There was nothing mean or unworthy about George Allan. His outstanding ability and transparent honesty assured him of the respect and admiration of his colleagues. Throughout his life he was engrossed in the practice of medicine, and under the influence of a wide and varied experience he matured as a leader endowed with ripe judgment and engaging friendliness. Though not lacking in modesty or humility, he never forgot that he belonged to a learned profession and he acquitted himself with dignity and distinction."

Dr Allan died on Sept 8 and is survived by his two daughters. His last years were marred by personal sorrow. During the war his wife died, and his son, serving in the R.A.M.C., was drowned in an enemy troopship in the Far East where he had been taken prisoner-of-war.

RINGLAND GILMORE BOYD

M.C., M.B. BELF, D.P.H.

Dr R. G. Boyd, senior assistant medical officer of health for Gloucestershire, died on Aug 17, a few hours after a road accident, when the car he was driving on his official duties came into collision with a lorry on the Gloucester-Bristol road.

Ringland Boyd was the youngest of a well-known County Derry family, and his brothers and sisters have made distinguished contributions to the Services and the professions. Born in 1917, he was educated at Coleraine Academical Institution and Queen's University, Belfast, where he graduated M.B. with honours in 1941. The following year he joined the R.A.M.C. and he served in Africa, Sicily, and Italy. He reached the rank of lieutenant-colonel and he was awarded the Military Cross. After demobilisation he held the posts of assistant M.O.H. at Manchester and at Gloucester. In 1948 he took the D.P.H. and he was appointed to Gloucestershire last April.

J. K. McC. writes: "Ringland had an engaging personality, he had charm without being effusive, he had ability and yet he was modest. His senior and junior colleagues both admired him, for he had great strength of character and strong belief in the principles of freedom, honourable interhuman relationships, and justice. A keen tennis and badminton player he was an outstanding sportsman. As a friend he was loyal, dependable, and worthy."

Births, Marriages, and Deaths

BIRTHS

AGATE—On Oct 26 in London, the wife of Dr John Agate—a son.
DEWAR—On Oct. 26 in Newcastle upon Tyne the wife of Dr H. A. Dewar—twins, son and daughter.
GRAY—On Oct 28 at Strathaven Lanarkshire the wife of Mr T. G. Gray, M.C. F.R.C.S.—a son.
LOVETT DOUST—On Nov 5 at Croydon the wife of Dr J. W. Lovett Doust—a son.
ROGERS—On Oct 20, the wife of Dr S. C. Rogers—a daughter.
STROTHER-STEWART—On Sept 28 at Ashleigh Newcastle the wife of Mr C. R. Strother-Stewart F.R.C.S.—a son.
WILSON—On Sept. 21; to Dr Ruth Ainsworth wife of Mr W. W. Wilson F.R.C.S.—a son.

MARRIAGES

HERVEY-KIDMAN—On Oct 28 at Ickleford Herts William Allan Hervey F.R.C.S.E. to Caroline Maude Kidman.
ROBB-SMITH-PICKLES—On Oct. 10 at Oxford Alastair Hamish Tearloch Robb Smith M.D. to Margaret Muriel Pickles D.M.

DEATHS

BELL—On Oct 30 Claudia Anita Prout Bell M.B. Durh. aged 77.
BLENKINSON—On Oct 26 at Intarfa, Malta Frederick Linton Blenkinsop M.B. Lond. lieutenant-colonel M.S. retd.
BLUNT—On Nov 1 at Hastings Eleanor Dorothea Blunt M.B. Lond., D.O.B.S.
FRENCH—On Oct 28 Frank Austin French M.R.C.S.
MAYO—On Nov 1 at Cowes I.O.W. Thomas Alfred Mayo D.M. M.B. Camb., F.R.C.S. aged 75.

Settle Lecture

Prof L P Garrod is to deliver this lecture at St Bartholomew's Hospital London, E C 1, on Wednesday Nov 22, at 5 P.M., on the Reaction of Bacteria to Chemotherapeutic Agents

Conference on Maternity and Child Welfare

The annual conference of the National Association for Maternity and Child Welfare is to be held at Church House Westminster, on June 27, 28, and 29 instead of on the dates previously announced

International Congress of Clinical Pathology

This congress is to be held by the International Society of Clinical Pathology in London on July 16-20, 1951, under the presidency of Sir Lionel Whitby. Inquiries should be addressed to the secretary treasurer, Dr W H McMenemey, Maida Vale Hospital for Nervous Diseases, London, W 9

Research Defence Society

The society's 19th Stephen Paget lecture is to be given by Prof E D Adrian, O.M., F.R.S. on Wednesday, Nov 22, at 5.30 P.M. in the physiology lecture theatre University College, Gower Street London, W C 1. Professor Adrian's subject will be Experiments on the Nervous System

British Association of Physical Medicine

This association is to hold a meeting in London on Friday and Saturday April 20 and 21. The programme will include a lecture-demonstration on micro waves by Dr A C Boyle and a demonstration on ultrasonics. Further information may be had from the secretary of the association, 45, Lincoln's Inn Fields London W C 2

West Midlands Physicians Association

The inaugural meeting of this association was held in Birmingham on Oct 21, when Sir Leonard Parsons F.R.S., was elected president. Dr A P Thomson Dr J H Sheldon, Prof W Melville Arnott, Dr A. M. Nussey Dr S R F Whittaker, and Dr P P Stock members of the executive committee and Dr A. C. W. Whitfield secretary and treasurer

Ophthalmological Society of the United Kingdom

The annual congress of this society will be held at 1, Wimpole Street, London, W 1 on March 29, 30 and 31. Mr Maurice Whiting will deliver his presidential address, Mr L H. Savin, Prof G W Pickering Dr F Dudley Hart, Mr A. B. Nutt, and Prof E J Wayne will open a discussion on the Association of Ocular and Articular Disease and Sir Henry Dale O.M. F.R.S. will give the Bowman lecture

Congress of Anaesthetists

The 26th annual congress of anaesthetists sponsored by the International Anesthesia Research Society, will be held in London from Sept 3 to 7 1951

The members of the London committee are Dr R W Cope Dr Vernon Hall, Dr Ronald Jarman, Mr A. Charles King Dr C B Lewis Dr G S W Organe Dr C F Scurr, and Dr W D Wylie. Papers for presentation at the meeting should be sent before March 15 to Dr Cope University College Hospital W C 1

North of England Surgical Society

The membership of this new society includes surgeons from the North of England in an area corresponding roughly to the Northern Region—that is from Carlisle to Newcastle and from the Tweed to North Yorkshire. The office bearers for the first year are president, Prof F C Pybus (Newcastle) vice-presidents Mr Norman Hodgson (Newcastle) and Mr J E Monro (Carlisle) secretary Prof F H Bentley (Newcastle) treasurer Mr H Harvey Evers (Newcastle) members of the committee, Mr D C Dickson (Middlesbrough) and Mr H B L Levy (Sunderland) Prof G Grev Turner is an honorary member. Five meetings will be held in the session with the principal home in the Medical School in Newcastle but with meetings in other large towns in the North. At the opening meeting on Nov 10 Professor Pybus is describing experimental work on carcinogenesis

Colour Television of Operations

The New York Academy of Medicine has arranged for a series of operations to be televised in colour over a closed circuit

Ross Award

This award, which was founded in 1949 by the standing committee of the Ross Institute has been offered to Mr Mehmed Azz, C.B.E., chief health officer of Cyprus in recognition of his thirty years' work on the control of malaria, culminating in his part in the Cyprus anopheline eradication scheme

Family Life in Flats

The Minister of Health has appointed a subcommittee of the Central Housing Advisory Committee under the chairmanship of Mr Henry Brooke M.P. To examine social needs and problems of families living in large blocks of flats. Prof J M Mackintosh is a member of the committee and the joint secretaries are Miss M Empson and Mr J C H. Holden, Ministry of Health Whitehall, S W 1

Remedial Work Among School-children

A conference on school remedial work will be held at Victoria Halls Bloomsbury Square London, W C 1, from Jan 2 to 4 by the Ling Physical Education Association in cooperation with the Society of Medical Officers of Health (schools health service group). Particulars may be had from the general secretary of the association, Hamilton House, Bidborough Street W C 1

Hyde Award

The Research Board for the Correlation of Medical Science and Physical Education has given the William Hyde award of £300 for 1949 to Mr H H. Newell engineering superintendent in charge of the rehabilitation workshop of Vauxhall Motors, Luton for the skill and resource which he has shown in developing engineering occupational therapy. About 1500 disabled patients have passed through his hands and are now useful employees. Some of this work was described in his joint article in our columns (*Lancet*, 1948 ii, 699)

Homes and the Family

A conference on this subject is to be held by the British committee of the International Union of Family Organisations at Caxton Hall London on Thursday Nov 23 from 2.30 to 6.30 P.M. The speakers will include Dr J D Kershaw, who will open a discussion on housing and health. Inquiries should be addressed to the committee's hon. secretary, c/o British Social Biology Council Tavistock House South, Tavistock Square London W C 1

American Public Health Association

This association has given one of its 1950 Lasker awards to the International Health Division of the Rockefeller Foundation for its achievement in the control of infectious diseases—particularly hookworm, yellow fever, and malaria—and the education of health staffs throughout the world. Three other awards go to Dr G W Beadle professor of biology and chairman of the biology division at the California Institute of Technology for discoveries that might one day enable man to control transmission of the hereditary factors that invite disease to Dr George Papanicolaou of Cornell University, for outstanding contributions to the early diagnosis of cancer and to Dr E L Bishop director of health and safety for the Tennessee Valley Authority, for original and meritorious accomplishments in public health administration—particularly his striking record in reducing endemic malaria

Nurses' War Memorial Chapel

On Nov 2 the Queen opened the Nurses' War Memorial Chapel in Westminster Abbey and unveiled the memorial window by Hugh Easton. The Princess Royal was also present, and among those who attended the ceremony were the Prime Minister the Secretary of State for Scotland the Secretary of State for Colonial Affairs the Speaker of the House of Commons Lord Addison F.R.C.S. Mr Clement Davies Admiral of the Fleet Lord Cunningham and Field-Marshal Lord Alanbrooke. The chapel was furnished by the gifts of nurses and midwives through the British Commonwealth and Empire Nurses War Memorial Fund launched in 1946 by the *Nursing Mirror*. A second object of the fund is to provide postgraduate travelling scholarships for nurses and midwives of the British Commonwealth and Empire. For this purpose £100,000 is required of which £77,000 has already been received. The address of the fund is Dorset House Stamford Street London, S.E. 1

University of Aberdeen

(The following degrees have been conferred)

MD—I A Anderson, A D Macrae, Alexander Mair (with honours), I C Cowan, L G Tulloch
MB ChB—C U Webster, Rosamond Beattie (with honours), Elizabeth A F Priest, J G Stewart, D M McLellan (with commendation), Elizabeth P Bell, A M Blackwell, I M Brooker, W R Bruce, W R Buchan, J N Burry, D D Carmichael, J P Chadwick, S C Clifford, A M Cook, G J Cordice, G Duncan, A L S Duthie, A T Edwards, Jean McG Edwards, A L Florence, N G Fraser, D T Gordon, Dorothy Gray, K T Gruer, R T S Henderson, A F Henry, R W Hilton, N B Hopper, W I Horne, C R Innes, George Innes, G S Joss, Janina E Kopersha, A W Laing, R A Laing, G S Laird, Zofia K W Laszewski, Helen C Lawson, Garth Lorimer, A D Lyall, D S McConnach, D J McCulloch, W G MacDonald, Winifred W McDonald, A W McIntosh, William McIntyre, Ian Mackay, James McKay, Murdoch Mackay, K J Maclean, H N MacPhail, R T Macpherson, Norman Marshall, Valerie M Milne, R A Mitchell, D M Moir, J S V Mount, R R Mowat, Muriel J Mucha, D R Murray, N T Nicol, T A A Pearce, W J W Rae, Frances S Ritchie, Margaret Robson, Helen C de C Roll, N Z Sacks, H G Saunders, Alexander Sillars, L C Skinner, D M Slessor, I W J Strachan, James Strachan, Dorothy A Sutherland, K I Sutherland, Janina Z M Szamocki, A J Taylor, Katharine J Thicknesse, Isabella E M F Thomas, I D H Todd, Audrey M G Towns, E I Watty, Dolores F Webster, R D Weir

Royal College of Physicians of London

At a comitia held on Oct 26, with Dr W Russell Brain, the president, in the chair, Dr W G Wylle, Dr L B Cole, and Dr F Avery Jones were elected councillors

Dr V H Springett was appointed Milroy lecturer for 1952, his subject being An Interpretation of Statistical Trends in Tuberculosis. The Jenks scholarship was awarded to P M Scott (Epsom College)

The following were elected to the membership

A P C Bacon, M B Camb, G A Beck, M B Lond, E A Beet, L R C Leon, Brotmacher, M B Lond, N J Brown, M B Brist, W J G Burke, M B Sydney, R A Burston, M B Adelaide, F G Campbell, M B Lond, F S Carter, M D Camb, Sydney Cope, M D Leeds, Brian Creamer, M B Lond, G S Crockett, M B Camb, G W Cronka, M B Belf, B A D Curtin, M B Sydney, R G Epps, M B Sydney, L P L Firman, Edwards, M D Camb, A A Fraser, M B Sydney, J V Gordon, M D Adelaide, E P W Helps, M D Lond, Constance M Hesling, M B Lond, H D G Hetherington, M D Lond, major R M C Yee, Ip, M B Hong Kong, Pashupati Nath Laha, M D Patna, M W Leifers, M D Lond, Ronald Lwin, M B Calcutta, John Mackinnon, M B Sheff, R S Male, M B Birm, H G Mather, M D Western Reserve, M B Camb, Jagdish Manubhai Mehta, M B Bombay, Arabinda Bihari Mukharji, M B Calcutta, D R L Newton, L R C P C M Ogilvie, M B Lpool, C M B Pare, M B Camb, Margaret M Platts, M B Sheff, W L Sanders, M B Lpool, captain R M C George Selby, M B Sydney, D F Sharvill, L R C P R H Vines, M B Sydney, W V Wadsworth, M B Manc, Joan C Wells, M B Lond, G B Westmore, M D Melb

Licences to practise were conferred upon the following 154 candidates (128 men and 26 women) who have passed the final examination of the Conjoint Board

R G Adams, W V Agnew, D G E Allridge, D F A Aubin, J A C Bamford, Agnes R D Bartels, Ivor Blakeaway, R M Bland, M H S Bound, Betty B Boxall, Yvonne J Bradfield, G S Brindley, I M Brown, A A F Bryson, Patricia M Bushell, E P Cadbury, W H Callander, S J Carne, Mary A Carter, M W Cernjyn, Jones, H N Chambers, E H Cooper, Sheila D Cooper, C H Corby, R G Covell, Elizabeth P Cracroft, J R Currie, A J I Dacre, Mary G C A Dale, D F C Deacon, G R C Deacon, N S de Alwis, J H de Graeve, Helen M Dence, M A de Valero, Wills, J A Dickinson, P L C Dligorsky, S B Donigiewicz, J W Draper, Winifred B Drew, P G J Duncan, Brian Edwards, Ibrahim Ali, Ly Bahrawy, B R Ellis, Peter Engel, J E Epsom, M L E Esprit, J F A Everson, P V N Ezekwe, Mary U Franklen, Evans, Tristram Freeman, R E Graham, W S Griffiths, I M Guiver, T K Hardy, J G M Harrison, Robina Harry Ursula E E Henderson, P G Higgins, Donald Hines, G C A Holden, J M Holden, P F B Holmes, W D Hopkins, Harry Horwitz, Desirale M G Howells, St C M L A Hubbard, P E Huddy, E M Hume, Anne L Hunter, Flsie S Jalkanen, Antoni Jedrzyszczak, M H F Johnson, Pamela M Johnson, E T J Jones, R J B H Jones, Norman Kaye, P H Kendall, D G Kibblewhite, D E W Knight, F W Knowles, Robert Korn, J P Lavender, A C K Lawrence, Eileen Lawson, Matthew A D Leschen, Mair E Lewis, Margaret E Lloyd, D H M Lord, R J Lunniss, Neil MacDonald, K M McFadyrean, K E MacLachlan, A D MacLaughlin, A R May, D B Mellins, R P Michael, Gerald Miller, B K Montgomery, Jean E Moore, Margaret C R Moore, Doreen P Morgan, J G Norman, R G Owen, H J G Palmer, Mary Parsons, D L Pedersen, B W Petty, H F Pile, E N Plomer, H F W Pribram, J K Price, R B Pridie, J H Ratcliffe, J H Reading, R B O Richards, Margaret M Ronch, B A Roberts, A L Ross, J W Rotenberg, J J H Rymer, H N St John, Barbara J Salisbury, J F Santer, F B Sartory, S A Sellman, I M Sharpe, I M Simmonds, E M E I Sondervorst, N E Stebbings, P P Stephens, K H Stone, J D Sutcliffe, R A Sutherland, L R Sweetman, S S Swift, GINETTE M Tebbutt, I B Thomas, P K Thomas, H T Thompson, D J G Tilley, J A Tottle, Rachel E Turner, Raymond Vickers, F H Walker, I H Wallington, A V Watts, W I White, Philippa M D Wigan, J L Williams, R A Williams, J B Williamson, J P W Young, T M Young

The following diplomas were conferred conjointly with the Royal College of Surgeons

DCH—R P Aronson, Anne L Barlow, Dorothy V Bignell, Savell Binder, Winifred M Bond, I S Booth, F S W Brimble

combe, Elspeth S K. Royal College of Obstetricians and Gynaecologists

The following have been admitted to the membership

G T Altimas, J D Andrew, P R Blahay, G T Carson, C J Champ, F L Clark, T R Clarke, W W Coppinger, B M Corliss, E D Crichton, Thomas Dean, C N DeGaris, William Donovan, H P Dunn, Isabel L Dyke, M W Filloitt, C J Farr, Balq Fatima, W R Foote, M B Fox, H H Francis, A C G Frost, W D Giffen, C A Haxton, H A Henderson, H F Hills, Robert Hodgkinson, R H Horner, D R Hughes, T G Ingram, D J McArthur, Irvine, H A Kelsey, Devaki Kutty, J F Leaver, J L MacArthur, D C McFwen, K T MacFarlane, Isabel M Macne, C M H Mah, W D Marshall, Helen M Noble, R H O'Hanlon, Doodana Goud, Prakash Paranjthy, M G Pearson, Ebr Quelli, Prins Daramarat, nam Rajaratnam, Indira Ramamurthi, K F J Read, H A Rowley, A M Rutherford, S A Scoror, D R Sheumack, E M Southern, D W Sparling, Subodh Kumar Sur, Roy Shri Nath Upadhyay, L G R Van Dongen, D B Beckwith, Whitehouse, Jael Willush, E A Williams, M H V Young

Royal College of Physicians of Ireland

The following were admitted on Nov 3 to membership of the college

N P Bector, W G D Caldwell, W W Ghali, D E Mellon and G H A Chamberlain

Royal College of Surgeons of Edinburgh

The following office bearers have been elected for the coming year: president, Mr W Quarry Wood, vice president, Mr Frank Jardine, secretary and treasurer, Mr J J Mason Brown, president's council, Prof R C Alexander, Mr K Paterson Brown, Mr John Bruce, Mr A J C Hamilton, Prof C F W Illingworth, Mr James Jeffrey, Sir James Learmonth, Mr Robert Mailer, Prof Walter Mercer, Mr T McWalter Millar, Mr Douglas Millar, Mr R Leslie Stewart, representative on the General Medical Council, Sir Henry Wade, conservator of museum, Mr J N J Hartley, conservator of museum committee, Mr Bruce, librarian, Mr Douglas Guthrie

The following have been admitted to the fellowship

Ewan Cameron, H McK Carey, A F Crook, A P McE Forrest, Alexander Hart, R F Hendtlass, R P Hewison, Shrinivas Dattatraya Joshi, R T S Loutit, J A Mantle, Nanubhai Gulababhai Mehta, H C Reid, Ahmed Rashid Ghonim Salem, J T Shearer, M N Tempest, Richard Yablonsky

Royal College of Surgeons of England

On Wednesday Dec 13 at 4 p.m., Mr William Doolan, FRCS, a member of the Royal Irish Academy, will deliver the Thomas Vicary lecture on Dublin's Surgeon anatomists

Royal Faculty of Physicians and Surgeons of Glasgow

The following have been admitted fellows of faculty quae physician, J D H Banker, Andrew Meiklejohn, and Mr Mousiquddin

Leeds Medical Dinner

The 60th annual dinner of past and present men students of the Leeds School of Medicine will be held at 7.30 p.m. on Friday, Nov 24, at the Great Northern Hotel, Leeds

SUPPURATIVE PNEUMONIA *

HOWARD NICHOLSON
M D Lond, F R C P

ASSISTANT PHYSICIAN, UNIVERSITY COLLEGE HOSPITAL,
CHIEF MEDICAL ASSISTANT, BROMPTON HOSPITAL,
LONDON

With illustrations on plate

I USE the term "suppurative pneumonia" to mean an inflammatory consolidation of the lung which proceeds in whole or in part to suppuration. This can occur in the course of certain specific pneumonias. There is also a large group of cases of suppurative disease of the lungs in which the organisms recovered are a mixture of types, none of them regarded as having invasive properties for the normal lung, and many of them indeed being found in the normal upper respiratory tract, it is to these that I intend to devote particular attention.

Specific Pneumonias

Pneumococcal Pneumonia

I wish first of all to describe certain features of those specific pneumonias which are associated with suppuration, to make clear their separation from the other group. In pneumococcal lobar pneumonia lung abscess is rare. Many writers have observed radiological features in the course of resolving pneumococcal pneumonia which they have regarded as simulating single or multiple abscesses (Graesser et al. 1934, Gleich 1932). Kessel (1930) described eight cases of this sort. Cecil and Plummer (1932) record an incidence of 0.4% and 0.5% in cases of type I and type II pneumococcal pneumonia, in 1000 cases of each type. Kessel attributed the lesion to thrombosis of an artery, and stated that the abscesses usually gave rise to no symptoms and healed rapidly and completely. Other authors (Gleich 1932, Massachusetts pneumonia series quoted by Heffron 1939) describe complete disappearance of the lesion in two or three weeks. It is, I think, reasonable to say that these abscesses in pneumococcal lobar pneumonia appear as translucent areas in radiographs taken during the stage of resolution. Although some may represent true cavities, they are not associated with the production of sputum and they rapidly disappear.

Staphylococcal Pneumonia

In staphylococcal pneumonia abscess formation is an important feature. The clear recognition of this we owe to the work of Brock (1945). Most of the other reports—for example, that by Chickering and Park (1919), whose cases were observed during the 1918 influenza epidemic—deal with an acute type of disease with a very high mortality after a short illness. Staphylococcal pneumonia has been most often described as occurring in influenza epidemics, and cases are recorded in which both influenza virus and staphylococci have been demonstrated in the pulmonary lesions (Scadding 1937), but sporadic cases do arise, particularly with other respiratory infections or during the course of chronic debilitating disease.

Its onset, as described by Chickering and Park, is insidious and rarely accompanied by the rigor and localised pain of pneumococcal lobar pneumonia. Prostration is an early feature, with high remittent fever but relatively slow pulse rate. Physical examination in the early stages often shows little abnormality, though radiographs usually reveal scattered opacities which may be widely distributed in both lung fields or confined to one lung or lobe. In this phase the sputum is usually scanty, purulent, and not foetid. It is described by

Chickering and Park as resembling anchovy sauce, but this is by no means common, and it is often simple pus from which a pure growth of *Staphylococcus aureus* can be obtained. During the winter of 1948-49 I observed three cases in which death occurred less than twenty-four hours after the onset. In two there was scattered consolidation throughout both lungs, while in the third the consolidation was confined to the left lung. In none of these was abscess formation evident clinically or radiologically.

There is, however, a less rapidly overwhelming variety of the infection, and it is in this that abscess formation becomes clinically recognisable. The fever may continue high and remittent, but commonly it settles, only to rise irregularly during the progress of the disease. The sputum usually increases gradually and other organisms are found in it. The radiological appearance alters, and in the pneumonic areas either single or multiple abscess cavities appear. Brock (1945) has pointed out that these are characteristically empty or almost empty, and present a thin walled, soap bubble appearance, particularly when they are situated in the midst of apparently normal lung. An abscess may rupture into the pleura and produce a pneumothorax—an event more common in infants than in adults. Clear pleural effusions may also occur as well as empyemata.

The stage of abscess formation may continue chronically, and the bacterial flora of the sputum then becomes indistinguishable from that of non-specific pulmonary suppuration. In other cases the inflammatory process subsides, but when this happens the large distension abscesses characteristic of the condition are often slow to disappear, and occasionally they persist and are wrongly regarded as congenital cysts.

Abscess formation in the lungs may also be due to staphylococcal pyæmia from a focus elsewhere in the body. Typically the abscesses in this condition are multiple, small, and empty, but clinically and radiologically the distinction from the abscess phase of staphylococcal pneumonia can be very difficult. The treatment of both types is the same: the avoidance of surgical drainage and the giving of sufficient penicillin.

The following case shows some of the features I have been describing.

Case 1—The patient, a boy aged 15, was admitted to the Brompton Hospital early in February, 1947. His illness had begun in mid-January with fever, cough, and a little sputum. He was kept in bed at home until late January when he was admitted to his local hospital. During this time he remained highly febrile and had developed septic sores on his left forearm and right foot. His left knee had also become swollen and tender, and his left thigh painful.

On admission he was flushed, drowsy, and very ill. His temperature varied between 101° and 103°F. He had a cough with very little purulent sputum. He was complaining of pain in his left knee, which was swollen, and he also had a swelling on his left thigh. Radiographs a few days before admission (figs 1 and 2) showed an enormous abscess cavity with a fluid level in it in the upper part of the right lung. In the film taken on admission the appearance suggested that there was also some fluid in the right pleural cavity. This pleural cavity was aspirated and 12 oz. of pinkish thin pus obtained, from which *Staph. aureus* was grown in pure culture. Sulphamezathine and penicillin courses were begun and penicillin was instilled into the right pleural cavity at the end of the aspiration.

The patient rapidly improved, a week after admission his temperature became normal and it remained so. Ten days after admission radiographs showed the abscess to be slightly smaller, at this time his sputum increased to 4 oz. a day. Penicillin was stopped after three weeks, when the patient was well his sputum having diminished to only a trace each day. A radiograph (fig 3) taken a month after admission shows the pulmonary cavity remaining as a thin walled cyst.

The boy went home and has since remained in good health. The closure of the pulmonary abscess cavity was watched

* The Goulstonian lectures for 1950, delivered at the Royal College of Physicians on Jan. 10 and 12.

Medical Care in Korea

On his return from Korea last month, Major General Raymond W Bliss, surgeon general of the U S Army, remarked that, during the campaign there mobile surgical hospitals in the forward areas had recorded less than 1 death for every 100 admissions. It seemed that the record in the late war, when three out of every four wounded admitted to hospital were returned to duty, might be surpassed in this campaign. Admissions for disease were only slightly higher than those for wounds and non battle injuries.

Analgesia in Domiciliary Midwifery

At the end of 1949, altogether 6674 of the 7864 midwives working in the domiciliary midwifery service of the local health authorities had been trained in the use of analgesics, compared with 6065 six months earlier. The number of gas and air machines available to domiciliary midwives increased during the second half of the year from 4729 to 5425, and analgesia was given by midwives in 69,915 cases, compared with 58,969 in the first six months of the year and 40,177 in the second half of 1948.

London County Council

Dr Verner Wiley, a senior medical officer in the L C C public health department, has retired.

Dr Wiley qualified M B R U I with honours in 1909 and four years later he graduated M D with first-class honours and the award of a gold medal. He gained the D P H with honours in 1920 and in that year he joined the L C C as an assistant medical officer in the school medical service. Subsequently he was in charge of a remand home and he prepared the first comprehensive reports on juvenile delinquency. For the last fifteen years he has controlled the branch responsible for the medical examinations of the council's staff and for the medical examination work in relation to mental ascertainment under the Mental Deficiency and Education Acts.

Sir Henry Tidy has been appointed a commander of the Belgian Order of the Crown.

Dr G S W Organe, anaesthetist to Westminster Hospital, is on a lecture tour, arranged by the British Council, of Italy, Turkey, Syria, and the Lebanon.

The Royal National Hospital for Rheumatic Diseases, Bath, have published the third volume of their reports, which contains reprints of papers published by the staff in 1948-49.

Doctors can now obtain a free copy of the 1950 register of speech therapists from the Board of Registration of Medical Auxiliaries, B M A. House, Tavistock Square, London, W C 1.

The British Rheumatic Association has published the first issue of a quarterly journal—the *B.R.A. Review*—intended for lay readers. The association's headquarters are at 5, Tite Street, London, S W 3.

The interim Report on the Future Provision of Medical and Allied Services (1920), commonly known as the Dawson report, which has been out of print for many years, has now been reprinted by the King Edward's Hospital Fund for London, with the permission of H.M. Stationery Office. Copies may be obtained from the fund, 10, Old Jewry, E C 2.

The business established early this century by George F Merson, an Edinburgh pharmacist, for the manufacture of sutures was acquired in 1947 by Messrs Johnson & Johnson. Under the name of Mersons (Sutures) Ltd it began to use the trade mark 'Ethicon,' and its name has now been changed to Ethicon Suture Laboratories Ltd.

The explanatory booklet *Superannuation Scheme for those engaged in the National Health Service*, which was published in 1948, has now been revised. The new edition includes changes made in the original scheme by amending regulations. New entrants to the service will be given a free copy of the booklet, which is also on sale at H.M. Stationery Office (3d).

Once again the Grenfell Association of Great Britain and Ireland will be selling Christmas cards depicting various aspects of life in Labrador. An illustrated leaflet reproducing the 13 cards and the label available can be obtained for 1d from the secretary at 66, Victoria Street, S W 1. All profits from the sale of the cards will be devoted to the association's medical work among British settlers in Labrador and Newfoundland.

Diary of the Week

NOV 12 TO 18

Monday, 13th

MEDICAL SOCIETY OF LONDON 11, Chandos Street, W 1
8 30 P M Dr C H O Toussaint Dr Alec Wingfield Demociliary Management of Pulmonary Tuberculosis.

11 30 A M Mr L B Patrick Genital Prolapse

was displaced to the left, and the left dome of the diaphragm was raised, there seemed also to be cavitation in the upper part of the lesion. Numerous examinations of his sputum for the tubercle bacillus were negative. His condition became steadily worse, and the consolidation in his left lung even more extensive. It had proved impossible by the usual means to grow organisms from his profuse sputum, but by appropriate methods of culture a pure growth of a microaerophilic non-haemolytic streptococcus was obtained. This was penicillin sensitive, and a course of penicillin, 50,000 units three hourly, was begun.

By the end of October he was greatly improved clinically, his sputum was reduced from 15 oz to 1 drachm each day, and his radiograph showed considerable clearing. He continued to improve steadily, and when the course of penicillin was stopped five weeks after his admission he was free from sputum.

He was discharged home six weeks later, symptom free and having gained 22 lb in weight during his stay in the sanatorium. Since then he has remained well, apart from occasional colds, and radiographs of his chest show that there is some residual fibrosis confined to the left upper lobe.

Other Specific Infections

Other specific infections besides those due to bacteria produce suppuration in the lung. Thus, cases of lung abscess due to *Entamoeba histolytica* are described (Harrington 1930). Histoplasmosis (Parsons and Zaronetis 1945) and coccidioidomycosis (Winn 1941, Greer and Grow 1949) may cause pulmonary abscesses, but this has not been reported in this country. Actinomycosis, although very rare (Macnab 1945), is the only fungus infection of importance here. It often presents as a chronic pneumonia (Pope 1946, Decker 1946) associated with purulent sputum and multiple small pulmonary abscess cavities. Its diagnosis is difficult, and in the reported cases it was not uncommon for several months or even years to elapse before the organism was demonstrated in sputum or—perhaps more commonly—in pus draining from chest wall sinuses.

BRONCHOGENIC CARCINOMA

Another group of cases of pulmonary suppuration, which I think are best considered separately from the non-specific group, are those related to bronchogenic carcinoma. Maxwell (1934) studied the post mortem findings in 315 cases where suppuration had occurred in the lungs, and he divided this series into two groups according to whether abscesses were single or multiple. He found bronchial carcinoma in 32 cases of the single abscess group, which comprised 109 cases, and in 2 of the multiple abscess group of 116 cases. In addition, in the first group there were 13 cases, and in the second group 3 cases, in which oesophageal carcinoma had invaded the lung. Thus in 50 cases pulmonary suppuration was related to intrapulmonary growths—an incidence of 15.9%. In Brock's (1948a) series of 405 cases of lung abscess, bronchial carcinoma was the cause in 56—an incidence of 13.8%. As Maxwell points out, most articles on pulmonary suppuration deliberately exclude consideration of intrathoracic malignant disease. Since most of these articles are concerned with clinical aspects and particularly with treatment, this is not unreasonable, for the prognosis and treatment in such cases are those of the malignant disease rather than of the pulmonary suppuration, although the suppuration may greatly influence the course of the illness and may modify treatment. Nevertheless, perhaps partly because of this exclusion, the very important association of bronchial carcinoma with pulmonary suppuration is inadequately recognised. This association is most common in middle-aged and elderly patients and Brock found that of his 56 patients with a lung abscess due to bronchial carcinoma, 53 were over 45 years of age.

It has for some time been recognised that there are two main ways in which bronchial carcinoma may produce abscess of the lung. The first is by breakdown

of the growth itself. As Tudor Edwards (1946) pointed out, it is commonly the squamous cell type of growth that breaks down in this way, and the abscess so formed has characteristically a thick and often irregular wall. The second way is by infection of the lung distal to the bronchus obstructed by the growth. It is interesting that, although obstruction of a bronchus by a foreign body is regarded as a frequent cause of lung abscess, Brock (1947c) found it only 3 times in 363 cases. On the other hand, bronchial carcinoma is so commonly related to lung abscess that in middle-aged and elderly patients with pulmonary suppuration the possibility of neoplasm must always be borne in mind.

Non-Specific Suppurative Pneumonia

The remainder of these lectures is devoted to certain aspects of those cases in which specific aetiological factors are not found. In the last twenty years at any rate reports on non-specific pulmonary suppuration have been written mainly by those whose interests are primarily surgical. The one important exception is the article by Maxwell (1934), which is based on a study of post mortem material. The cases most frequently described are, therefore, those in which abscess cavity formation was the outstanding clinical and radiological feature, or those which were fatal. Such descriptions do not, I believe, give a complete picture of non-specific pulmonary suppuration. It is more reasonable to regard lung abscess as the most severe variety of a whole range of aspiration pneumonias, at the opposite extreme are those benign localised pneumonias associated with upper respiratory infections. In order to support this view, I propose to review some of the evidence that infected material may be aspirated into the bronchial tree and produce pulmonary changes, and to give examples of aspiration pneumonias of varying severity.

BENIGN ASPIRATION PNEUMONIA

In 1939 Ramsay and Scadding published an account of 21 cases seen in two years at a tuberculosis clinic. These cases were characterised by the association of mild respiratory catarrhal symptoms with transient radiographic shadows in the lungs. They referred to the work of Quinn and Meyer (1929) and of Amberson (1937), who showed that iodised oil introduced into the noses of sleeping subjects could next morning be demonstrated radiographically in alveoli. Further, they quoted Gunn and Nungester (1936), who, in the course of attempts to produce experimental pneumococcal pneumonia in rats, were able to produce transient pneumonia by the intra-bronchial injection of mucus alone. It seemed therefore possible that mucus, either from the upper respiratory tract or of bronchial origin, might obstruct bronchi or bronchioles and produce the sort of mild transient pneumonia which they had described. As Scadding (1948) has pointed out, these transient shadows are very often seen in patients with chronic bronchitis, asthma, or chronic abnormalities of the upper respiratory tract causing excessive secretion, as well as with acute respiratory catarrh. It is, I believe, now generally accepted that these transient radiographic appearances are best interpreted as aspiration pneumonias. In these cases the sputum usually contains only those types of bacteria which may be found in the normal upper respiratory tract, and none of these is specifically invasive for the lungs. In these circumstances, the bronchial or bronchiolar block producing atelectasis beyond the obstruction is the more important factor. The inflammatory reaction produced in the airless lung by the bacteria present in the blocking mucus plug is slight and rapidly proceeds to complete resolution.

ASPIRATION IN PATHOGENESIS OF LUNG ABSCESS

In discussions of the pathogenesis of acute abscess of the lung, the main controversy has been whether it was

radiographically, and by June, 1947, there was no evidence of a cavity

Friedländer's Pneumonia

Another of the specific pneumonias in the course of which abscess formation may occur is that due to Friedländer's bacillus. Pneumonia due to this organism is rare—in large series of all varieties of pneumonia (Solomon 1937, Bullowa 1937, Heffron and Varley 1932), approximately 1% have been due to this organism. The illness is usually severe with a very high fatality. A more chronic form has, however, been recognised for many years. Thus, Belk (1926), who investigated a group of cases which came to autopsy, described three as "chronic suppurative pneumonitis," and stated that the course of the disease was similar to that of pulmonary tuberculosis. Brock (1946) found reports on eighteen cases, to which he added two of his own, in which the acute specific pneumonia of Friedländer's bacillus "did not end fatally but broke down to form abscesses and assumed a chronic suppurative course."

The course of Friedländer's bacillus pneumonia has been described by Collins and Kornblum (1929). They regard the earliest stage as a lobular pneumonia. The lobular areas coalesce and produce more massive consolidation, which is not usually confined by lobar boundaries. Several such areas may be present in one or both lungs, and Collins and Kornblum apply to this type of consolidation the term "pseudolobar pneumonia." In these areas the lung is extensively destroyed, with the production of abscess cavities, and at this stage the disease usually ends fatally.

Clinically the onset is sudden. The patient is severely ill with a fever which does not usually rise above 102°F. There are usually few abnormal physical signs in the chest, but there is often a leucocytosis, the white cell count reaching 15,000 per c.mm., with a polymorpho-nuclear percentage of about 85 (Belk 1926). The sputum is tenacious with little odour and contains the organisms in large numbers.

Thus, the possibility of Friedländer's bacillus as the causal organism must be borne in mind when abscess formation occurs in areas of massive consolidation during acute pneumonia. In chronic pulmonary suppuration also, this organism must be remembered, perhaps particularly in cases resembling pulmonary tuberculosis but in which the tubercle bacillus cannot be found. This has become even more important since the introduction of streptomycin, which has proved effective against experimental infections with Friedländer's bacillus (Heilman 1945). There are also some records of its clinical use in pulmonary infection with this organism (Harris et al 1947, Hennell and Nicholls 1945).

The following case was treated with streptomycin, and apparently complete resolution occurred.

Case 2—A labourer, aged 33, had for many years had a cough with some sputum, and on demobilisation from the Army had been told that he had chronic bronchitis. He had felt well and was doing heavy work until five days before admission to University College Hospital, when he had suddenly developed pain in the right side of his chest. He felt ill and had a headache, his cough became worse, and the following day he coughed up sputum which was mixed with bright blood. During the next day or two his sputum became purulent.

On admission he was very ill, he was febrile to 102.4°F, and he was coughing up 2 oz of purulent, often blood stained, sputum each day. Abnormal physical signs were confined to his right upper chest, where the percussion note was impaired and bronchial breath sounds with a few fine râles were heard. A radiograph (fig 4) showed consolidation in the upper part of the right lung and in the lateral view this was seen to be mainly in the apical and posterolateral segments of the upper lobe. Next day treatment with penicillin, 100,000 units every three hours, was begun. This was not followed by any change in his general

Fig 5—(Case 2) Friedländer's pneumonia temperature chart.

condition, but his temperature fell to 99.6°F. After two more days the results of his sputum examination became available and showed the presence of a mixed flora in which Friedländer's bacillus was predominant. This organism was isolated from a second specimen of sputum and when injected intraperitoneally in a mouse caused death in twenty-four hours. It was found to be penicillin resistant, moderately sensitive to sulphonamides, and sensitive to streptomycin.

The patient was given a six day course of sulphathiazole. This produced no change in the clinical condition, and a radiograph showed extension of the consolidated area apparently throughout the upper lobe. Streptomycin was then started at a dosage of 1 g eight-hourly, and was continued for seven days. His temperature-chart (fig 5) shows that the fever rapidly settled, and his clinical condition quickly improved. Sputum diminished in amount, ceased to be bloodstained, and became tenacious in consistency. Tomography (fig 6) showed cavitation in the consolidated area. The radiological opacity gradually cleared, and further tomograms three weeks later failed to show cavitation.

The patient was discharged, and when seen again a month later he was well and had a normal radiograph.

Micro aerophilic Non haemolytic Streptococcal Pneumonia

Apart from pulmonary tuberculosis, which may be regarded as a specific pneumonia associated with abscess formation, the types described above are the main specific bacterial pneumonias which produce suppurative changes in the lung. Possibly, however, more careful bacteriological investigation in cases which are regarded as belonging to the non specific group may show that there are other bacteria which may be specifically invasive for the lungs and capable of causing abscesses. The following case is interesting in this connection.

Case 3—A man, aged 33, was taken ill in March, 1947. The onset of the illness was insidious, with a little cough and mucoid sputum and some pain in the left side of his chest. He was seen at his local tuberculosis clinic where a radiograph of his chest (fig 7) showed an opacity in the left mid zone. He continued to work, but felt increasingly ill and two months later he was coughing up 2 oz of purulent sputum each day. Examination of his sputum for the tubercle bacillus was negative. He rested at home until September 1947—six months after the beginning of his illness—when he was admitted to the Brompton Hospital Sanatorium.

His general condition then was poor. His evening temperature was 99°F, and he was coughing up 10–15 oz of thick, purulent sputum each day. His fingers were clubbed. Radiographic examination (fig 8) showed that the consolidation in the left lung was much more extensive, the mediastinum

DR NICHOLSON SUPPURATIVE PNEUMONIA

due to aspiration of infected material or to the lodging of infected blood borne emboli in the lungs. The views expressed up to the year 1934 have been well summarised by Maxwell. Observations such as those I have quoted in relation to the benign pneumonias associated with catarrhal infections of the respiratory tract, leave little doubt that aspiration of material into bronchi and bronchioles can take place, and that it can produce inflammatory changes in the lung. What has been in dispute is whether the aspiration of infected material can by itself produce suppuration and abscess formation, or whether arterial embolism is necessary, either as an accessory or as the primary cause. On this point experimental studies in animals have, I think, been inconclusive, some supporting the view that arterial embolism is necessary (e.g., Cutler and Solliueter 1926, Herrmann and Cutler 1929, Holman 1926), whereas other workers (Joannides 1928, Hedblom et al 1928) were able to produce abscesses by aspiratory methods alone. In man one of the chief objections to the aspiration theory has been the observation that abscesses are commonly situated in the upper lobes. Thus, in a series of 25 cases of pulmonary suppuration observed by Logan and myself (Logan and Nicholson 1949), radiographic evidence of the original situation of the disease was available in 22, and of these the suppurative process involved the upper lobes in 15 instances, 10 on the right side and 5 on the left. Such findings have been thought to support the vascular embolism theory, since it was expected that the aspiration of infected material would produce lower-lobe abscesses mainly.

Many authors (e.g., Touroff and Moolten 1935, Stern 1935) have recorded the frequent association of lung abscess with suppurative processes in the mouth and pharynx, particularly in relation to the teeth and gums, and in the tonsils, and have asserted that aspiration of infected material from these sites is the most common cause of pulmonary suppuration. It is, however, to the work of Brock that we owe the clearest exposition of this view and the one most carefully and fully supported by observed facts. In 1942, with his co-workers, he published an account of experiments in which a small amount of iodised oil was introduced into the trachea with the subject lying on his side or on his back. Radiographs taken at suitable intervals showed that the oil came to rest in the posterior and axillary parts of the upper lobe and in the apical segment of the lower lobe. These are the commonest sites in which abscesses are found, and, as Brock explains, their localisation in these parts of the lung is easily accounted for by gravity, posture, and the anatomical arrangement of the bronchial tree. In subsequent papers (Brock 1947a, b, and c) he has elaborated with a wealth of examples these factors of posture and bronchial anatomy. In sleep, during and after anaesthesia, or in coma, the patient is usually horizontal, and it is at these times that conditions are most favourable for inhaling infected material into the bronchi.

The distribution of abscesses in the lung may, therefore, be held to support the aspiration theory of their causation. The frequent association of pulmonary abscess with suppurative processes in the upper respiratory tract may also be regarded as presumptive evidence in favour of this view. The association with tonsillectomy has been recorded in many papers. Pinchin and Morlock (1930) found that of their 16 cases, 4 arose after this operation. Flick and his colleagues (1929) described 172 cases of which 97 followed tonsillectomy, and of 158 cases described by Touroff and Moolten (1935) 25% followed this procedure. The importance of dental operations and dental sepsis in relation to the causation of lung abscess has been very clearly shown in the writings of Stern (1935, 1936), who found that of 70 consecutive cases at the Mount Sinai Hospital, New York, 12 followed

dental operations. In another series of 115 cases, 13 followed dental operations, in this group there were 74 cases in which the aetiology was obscure, but further investigation of these showed that in 84% there were infected gums harbouring debris, anaerobic organisms, and tartar. Brock (1947c) has especially emphasised the importance of dental sepsis, and in his series of 316 cases of non-malignant lung abscess, gross dental sepsis was regarded as being responsible for 19%. Further sources of infected material that have been described include sinusitis, quinsy, and other respiratory tract infections. Bronchiectasis is also an occasional cause.

The occurrence of lung abscess after abdominal operations has been commonly held to support the view that vascular embolism is the cause. Thus, in Maxwell's (1934) series of 199 single abscesses, 38 followed abdominal operations. His comment is "that there is an intimate connexion between the occurrences of lung abscess and the presence of sepsis in the operative field, an observation which points to an embolic origin for the majority of cases at least." On the other hand, the frequency with which these abscesses are associated with dental sepsis, and the fact that circumstances during the period of recovery from anaesthesia are ideal for aspiration, make it at any rate equally possible that in the majority of cases this, and not vascular embolism, is the cause.

On the whole the evidence supports the aspiration theory, and few who frequently see cases of pulmonary suppuration doubt that in most instances these are due to the inhalation of infected material into the bronchial tree. As in the cases of benign aspiration pneumonia described by Ramsay and Scadding (1939), this is followed by occlusion of a bronchus or bronchiole and atelectasis beyond the block. The infecting organisms meanwhile produce an acute inflammatory process and suppuration in the airless lung tissue. Once suppuration has occurred, the abscesses, either large or small, discharge into the bronchial tree and purulent sputum results.

SUPPURATIVE PNEUMONIAS OF INTERMEDIATE SEVERITY

If, therefore, it be accepted that acute lung abscess and the transient pulmonary lesions associated with respiratory catarrh are both examples of aspiration pneumonia, then it seems reasonable to include in this group a number of pneumonias of varying severity which are commonly seen in the medical wards of general hospitals. These may be regarded as occupying an intermediate position between the transient pulmonary consolidations and acute lung abscess. I propose to describe briefly three such cases.

Case 4—A woman, aged 21, was admitted to University College Hospital in September, 1949. Previously, apart

from frequent colds each winter, she had been healthy. About a fortnight before admission she had begun to have one of her usual colds, with nasal discharge and slight soreness of her throat. After two or three days she began to cough and to bring up a little sputum, which gradually increased in amount. On admission she was febrile to 101°F and was coughing up 2-3 oz of mucopurulent, but not foetid, sputum each day. Rib movement was reduced at the left lower chest, and numerous coarse râles were heard at the left base posteriorly. Radiographs (figs 9 and 10) taken on the day of admission showed consolidation at the left base, probably in the middle basal segment of the left lower lobe. Examination of the sputum showed the presence of a mixed flora, including *Streptococcus pyogenes* and a coliform bacillus.

She received sulphamezathine and penicillin, and had postural drainage and coughing under the supervision of a physiotherapist four or five times each day. She slept at night with the foot of her bed raised, and as far as possible in a position likely to drain the affected segment. Her temperature became normal the next day, and after six days she had only a trace of sputum. Radiographs taken ten days after admission showed normal lung fields, and she was discharged well and free from symptoms.

Case 5—In this example, the patient, a woman aged 35, had a similar history of acute respiratory catarrh with cough and the production of 3-4 oz of mucopurulent sputum. She was seen as an outpatient at University College Hospital in August, 1949, when radiographs (figs 11 and 12) showed consolidation involving probably all the basal segments of the left lower lobe, with some collapse of these segments. On similar treatment she cleared up in a few days, and her radiographs showed normal lung fields. In her case also, the sputum contained a mixed flora without predominance of any particular organism.

Case 6—In the third example the patient was a man, aged 52, who was admitted to University College Hospital in May, 1949. He had been well, apart from occasional morning cough, until eleven weeks before admission, when he had had a severe cold with nasal discharge and pains in the limbs. He had then stayed away from work for three days, but after his return his nasal catarrh continued and he felt unwell. On admission he was in good general condition with a fever to 99°F in the evenings. Ten days before he came into hospital he had coughed up about 2 oz of thick pus and had continued after this to bring up a similar amount each day. On examination this was not found to be foul smelling, it contained a mixed flora and among other organisms a coliform bacillus and a member of the hemophilus group were grown. He had no abnormal physical signs and was edentulous, his teeth having been extracted many years before. A radiograph of his chest (fig 13) showed an area of consolidation, which was in the axillary parts of the antero-lateral and posterolateral segments of his right upper lobe. Bronchoscopy was carried out and the right upper lobe orifice found to be normal; the segmental orifices were patent but covered by mucus. Treatment with postural drainage and chemotherapy was rapidly followed by decrease in the amount of his sputum. He was discharged free from symptoms after three weeks. His radiographs did not, however, clear completely. Six months later, when he was still quite free from cough and sputum, radiographs showed the transverse fissure to be slightly drawn upwards and a small opacity above it, probably due to some fibrosis in the upper lobe.

ACUTE SOLITARY LUNG ABSCESS

For comparison with these relatively benign conditions, I propose to describe two examples of acute lung abscess.

Case 7—In the first, the patient was an Army officer, aged 23, who was admitted to hospital in March 1943, with an acute right-sided streptococcal thoracic empyema. This was treated and complete re-expansion of his right lung obtained. It was clear from his history that he had had a cough, with about 1 oz of purulent sputum each day, from childhood, and he had had frequent episodes of severe respiratory infection. His sputum persisted after the empyema had healed completely. Coarse râles were heard over his right lower chest posteriorly. Bronchograms (figs 14 and 15) showed dilatation of the right basal bronchi. The left bronchial tree was normal. In view of his symptoms and the likelihood that the empyema was related to the bronchiectasis, it was decided that he should have a right lower lobectomy. He had been severely ill with the streptococcal empyema, and it was thought reasonable to wait a few months before undertaking the lobectomy. Accordingly, after the bronchograms had been made, he was sent away for six months' convalescence. After five months, however, he returned to hospital, very ill, febrile to 102°F, and complaining of pain in the upper part of his right chest posteriorly. His sputum had not increased in amount. A radiograph (fig 16) showed an area of consolidation which was in the posterolateral segment of the right upper lobe.

He was treated with sulphathiazole and postural coughing, but his sputum increased in amount to 4 oz a day, although his general condition improved and the fever settled. Examination of the sputum, which was not foetid, showed the presence of a mixed flora, including pneumococci, staphylococci and *Neisseria catarrhalis*; repeated examinations were negative for tubercle bacilli. A radiograph (fig 17) taken a fortnight later showed that the area of consolidation had apparently broken down and an abscess cavity had appeared. This was drained externally, and after healing had taken place bronchoscopy was repeated. This showed some distortion of the posterolateral branch of the right upper lobe bronchus, the bronchiectasis of the lower lobe remained evident, and there can be little doubt that pus was aspirated from the lower lobe into the posterolateral segment of the upper lobe and produced the abscess.

After having been well for two months, but still bringing up 1 oz of purulent sputum each day, he returned to hospital. He was again very ill, febrile, with profuse sputum, and his radiographs once more showed an abscess cavity in the posterolateral segment of the right upper lobe. This was drained, but he died of cerebral suppuration.

Case 8—In the second example, the cause of the abscess was apparently dental and gingival sepsis. The patient was a Royal Air Force officer, 44 years old, who was admitted to hospital in December, 1942. He was severely ill, febrile to 103°F, and coughing up 4 oz of foul smelling purulent sputum each day. He had been living in conditions of considerable hardship for several months, and had become gradually ill over the three weeks before his admission.

On examination his fingers were clubbed, there was an impaired percussion note and numerous coarse râles were heard over the upper part of his right chest. Radiographs showed a large abscess (figs 18 and 19) occupying most of his right upper lobe. This was drained externally. His symptoms were immediately relieved and he rapidly became afebrile and well. It was three months, however, before the abscess cavity was regarded as having healed and the drainage wound allowed to close. Bronchograms (figs 20 and 21) three months later showed that in fact, a small linear cavity remained in communication with the bronchial tree. Because of its situation, it seemed likely that its drainage would be satisfactory. The patient was well and free from cough and sputum.

It seems reasonable to regard such conditions as these that I have just described as aspiration pneumonias. In the three more benign instances the pneumonia followed a respiratory catarrhal infection, and the suppurative process which resulted was relatively mild and was overcome before demonstrable abscesses were produced. In the other two examples large abscess cavities were formed, presumably because of the more virulent nature of the invading organisms or the impaired resistance of the patient. In the first of these the organisms were

THE administration of either pituitary adreno-corticotrophic hormone (ACTH) or synthetic 'Cortisone' acetate produces a striking amelioration of symptoms in patients with rheumatoid arthritis (Hench et al. 1949, Thorn et al. 1949, Markson 1949, Spies and Stone 1949, Spies et al. 1949, Ragan et al. 1949, Sprague et al. 1950). The major therapeutic effect of ACTH on human beings is caused by the steroid hormones which are produced when it stimulates the adrenal glands. Some of these hormones are closely related to cortisone. With other investigators, we suspect that the administration of large amounts of ACTH to human beings over long periods may be harmful through excessive stimulation.

Cushing's syndrome, associated with hyperplastic or neoplastic adrenal cortices, was described before cortisone and ACTH were administered in large amounts to man. It is characterised by acne, hirsutism, amenorrhoea in females, mental symptoms, raised blood pressure, alkalosis, cutaneous striae, negative nitrogen balance, decreased carbohydrate tolerance with glycosuria, and decrease in circulating eosinophils. Certainly these symptoms tend to follow either the administration of large amounts of cortisone over a long period, or protracted therapy with ACTH, owing to the overproduction of cortisone and cortisone-like hormones by the adrenal cortex. In some patients with Cushing's syndrome arising from a tumour of one adrenal cortex there is atrophy of the other adrenal cortex. The atrophy of the contralateral adrenal cortex is presumably a result of the overproduction of cortisone or a cortisone-like substance from the neoplasm. Accordingly it is reasonable to assume that the administration of large amounts of synthetic cortisone for a long time may result in some degree of atrophy of the adrenal cortex.

Since rheumatoid arthritis is often a debilitating disease, and since either ACTH or cortisone ameliorates the acute symptoms, it seemed worth while to attempt to rehabilitate a group of patients in whom the disease was active and the resulting disability great. We decided to give each patient a series of injections of ACTH and on another occasion to give the same patient a series of injections of cortisone, the rationale being that one of these hormones overstimulates the adrenal cortices and the other tends "to put them to sleep." Because of their scarcity we could not give these materials at regular intervals. When the patients had acute symptoms and neither ACTH nor cortisone was

available, we gave them injections of pregnenolone acetate (5 pregnene 3 beta ol-20 one 3 acetate), deoxycortone acetate (DOCA) and ascorbic acid, physiological saline solution, or acetylsalicylic acid. In no case did pregnenolone acetate, deoxycortone acetate and ascorbic acid, saline solution, or acetylsalicylic acid give relief, whereas both ACTH and cortisone were definitely beneficial. Though the patients are still under study, their disability has decreased sufficiently to enable them to work.

MATERIAL AND METHOD

From a large group of patients with rheumatoid arthritis who had been under observation in the Nutrition Clinic we selected four men and three women. We excluded patients with mild arthritis or those who had ankylosis of the weight bearing joints or the joints of the hands and fingers. The seven patients selected fulfilled the following criteria: (1) severe physical handicap to an extent that they could not function without the assistance of others, (2) swollen painful tender joints, (3) a loss in body-weight and a distaste for food, (4) characteristic radiological evidence of arthritis, (5) a raised erythrocyte sedimentation rate, (6) anaemia characterised by 80% haemoglobin or less, and (7) normal uric acid level in the blood. To rule out those who might benefit from the administration of salicylates either orally or parenterally each patient was given an initial dose of acetylsalicylic acid grains 10 t.i.d., and the amount was increased until salicylism developed or gr 100 had been given in twenty-four hours. If the patients experienced no relief, and if no changes were detected in the physical examination or laboratory investigation, each patient was given 10 grammes of sodium salicylate intravenously daily for three days, followed by 20 g daily for three days. Patients who experienced relief of symptoms and some decrease in swelling were not included in the study. The seven who were selected finally were chosen because they seemed to be unusually determined to fight their disease and because they felt it necessary to resume a normal life. They were told that they would be subjects of an investigation, that they would not know what medication they were receiving, and that irrespective of the results obtained their treatment would be changed from time to time.

In the treatment of many patients with either ACTH or cortisone for malignancy, Hodgkin's disease, acute leukaemia, lymphosarcoma, or lupus erythematosus we have often found it necessary to administer very large doses of one or the other substance week after week to maintain life, with the result that we have had a rather broad clinical experience of the physiological responses to cortisone or ACTH given in massive doses (Spies et al. 1950). With this experience in mind we carefully sought any evidence of humoral effect in this series of patients. Each patient went through the following periods of observation:

- 1 Effect of frequent injections of physiological saline solution.
- 2 Effect of frequent injections of ACTH in saline solution.
- 3 Effect of sterile pregnenolone acetate in benzyl alcohol and saline solution.
- 4 Effect of acetylsalicylic acid orally and parenterally.
- 5 Effect of deoxycortone acetate and ascorbic acid with low sodium diet.
- 6 Effect of acetylsalicylic acid.
- 7 Effect of synthetic cortisone acetate.
- 8 Effect of parenteral deoxycortone acetate and parenteral ascorbic acid without restriction of sodium in diet.
- 9 Effect of synthetic cortisone acetate.
- 10 Effect of ACTH.

Each of these periods of study included several days of observation before, during, and after the administration of each of the materials. Blood-pressure, pulse rate, and body-weight were determined daily. In

† Clayton Foundation fellow.

probably earned in pus from bronchiectasis in another lobe, and the patient had not long recovered from a severe thoracic empyema. In the second the organisms were thought to have been carried in material from infected gums while the patient was subjected to hardship in the course of his duty. In the first the sputum was never at any time foul smelling, while in the second the patient coughed up foetid pus. This possibility of classifying pulmonary suppuration in foetid and non-foetid groups has engaged much attention in the past twenty years, and I should like to consider briefly its significance.

FETID AND NON-FETID TYPES

Touroff and Neuhoef (1941) emphasise the importance, as far as prognosis and treatment are concerned, of separating pulmonary suppuration into foetid and non-foetid types. It is doubtful whether this distinction can be made with any degree of accuracy. Brock (1947a), who uses these two types as being convenient in classification, states that the figures he gives for foetid and non-foetid abscesses are not "more than approximately accurate, the margin of error either way being possibly as much as 10 per cent." Further, he points out the difficulty of deciding from the patient's account of his symptoms whether or not the sputum has at any time been foul smelling. In the series of 25 cases of chronic pulmonary suppuration observed by Logan and myself (Logan and Nicholson 1949), foetor of the sputum was found to come and go, and was present at some time during the course of the disease in all but 4 cases. Similarly, Sellors and his colleagues (1946), in a series of 27 cases of chronic pulmonary suppuration, noted that in all but 6, the sputum was foetid at some time during the illness. In Brock's paper the foetid and non-foetid groups are considered in relation to prognosis. He found that a series of 238 cases could be divided into 126 in which the sputum was foetid and 112 in which it was not. In his study of these groups he stated that it was not his experience "that spontaneous resolution, with low morbidity and low mortality, and without serious permanent secondary changes in the lungs, is substantially more frequent in the group as a whole than in the foetid group."

In relation to treatment it seems equally difficult to maintain any need to attempt this distinction. Thus, Touroff and Neuhoef, although claiming that a foetid abscess should be treated by early external drainage while a non-foetid abscess should be treated conservatively, do regard one variety of the non-foetid group—namely, that which consists of a solitary abscess without surrounding inflammatory changes—as often requiring surgical drainage. The same principle has, in fact, commonly been applied to the foetid group (Brock 1948b, Shaw 1942), and it seems that the fact that the abscess cavity is solitary and uncomplicated by surrounding inflammatory changes may indicate surgical drainage, irrespective of whether or not it is regarded as foetid.

AEROBIC AND ANAEROBIC ORGANISMS

It has long been known that the foetid sputum of patients with lung abscess can be shown to contain spirochaetes and fusiform bacilli (Leyden and Jaffe 1867, Ron 1905). The relation of these organisms to the pathogenesis of lung abscess has been much disputed, and Maxwell (1934), in his summary of the bacteriological findings in lung abscess up to 1934, concludes that the condition can arise "from infection with one or more of a variety of organisms," and "the specificity of the spirochaetes and other anaerobic organisms" cannot be regarded as proved. Nevertheless, the work of D. T. Smith (1927, 1932) leaves little doubt that, in certain cases at any rate, anaerobic spirochaetal organisms are responsible for the production of lung abscess. He

demonstrated the presence of these organisms in the sputum and in the cavity walls of abscesses, and in addition produced abscesses in animals by the intratracheal injection of mixed cultures of these organisms. He also demonstrated their presence around the teeth of persons suffering from pyorrhoea, and he produced pulmonary abscesses in laboratory animals with material scraped from such teeth. On the other hand, pulmonary suppuration frequently occurs in the absence of dental sepsis, and the sputum of patients with lung abscess is almost as frequently non-foetid as foetid. Moreover, on culture of the sputum from cases of lung abscess, it is usual to find a mixture of aerobic organisms of the varieties commonly found in the mouth and upper respiratory tract (e.g., Bucher 1930), these organisms may often be the cause of the suppuration, but even in cases where suppuration is caused by anaerobes, once the abscess has ruptured into the bronchial tree conditions must encourage aerobic growth. Thus, I think that if the view be taken that there is a range of localised aspiration pneumonias from the most benign through varying degrees of suppuration to cases in which extensive abscess formation is an early feature, then it is likely that many of the more severe types are caused by anaerobic organisms. These are often soon overgrown because of the development of aerobic conditions. During the course of protracted pulmonary suppuration local conditions in the lung may from time to time encourage the growth of anaerobes, so perhaps accounting for the observation that foul sputum is a variable feature of such suppuration. In any case, it seems impracticable to distinguish foetid and non-foetid types of non-specific pulmonary suppuration, and as far as prognosis and treatment are concerned it does not seem important.

Pulmonary suppuration, once established, may progress as a chronic disease. In surveying non-specific suppuration, I have been concerned mainly with putting forward a unified view of its development. In the same way I regard the chronic phase as essentially a single entity. In most reports which refer to the chronic phase, an attempt is made to distinguish between chronic foetid and chronic non-foetid abscess. As Brock (1947a) points out, chronic suppuration in both groups "carries the same grave ultimate prognosis", and in fact, for reasons which I have given, I do not believe it possible to make the distinction with any accuracy. Further, cases which at their onset present as solitary abscesses do not differ materially in their chronic course from those which begin as a mainly pneumonic process (Logan and Nicholson 1949).

(To be concluded)

"Much too much has been said about the training of the medical student. Much too little about the training of the patient. Nothing, in fact. This country still hasn't got a Royal College of Patients. A single glance over the assembled crowd in Out Patients' Department should suffice to classify patients into two distinct groups: amateurs and professionals. Both groups are waiting. But there is a world of difference between them. Professional patients develop their symptoms gradually and with the tender care of a French chef preparing a major dish. Amateur patients keep on acquiring new symptoms and losing old ones as if they were fountain pens or library books. Professional patients will start their past history by remarking that they were eight-months babies. Amateur patients may remember having spent three months in hospital the previous year, but they can rarely tell whether the trouble was in their chest or in their tummy. And they will insist that neither could the doctors. Amateur patients have large and healthy families. Professional patients have never had time. Professional patients regard it as the highest aim of the medical profession to get them into hospital. Amateur patients naively but firmly believe that it is to get them out of it."—T. L. D. *Magazine of the Royal Free Hospital School of Medicine*, 1950, 12, 56.

Fig 2—Effect of cortisone on electrolyte pattern in rheumatoid arthritis.

acetate and ascorbic acid injections at the same time, and to restrict him to a diet containing not more than 200 mg of sodium chloride. After he had been on the diet for two days he was given deoxycortone acetate 10 mg intramuscularly and ascorbic acid 1 g intravenously daily for four days. At the end of this time the ascorbic acid was discontinued, but the deoxycortone acetate was given in the same dosage for fourteen more days. This therapy gave no relief whatever from the pain and stiffness of the joints. The patient did not develop oedema at any time. The B.P. increased slightly, ranging between 134/80 and 136/84 whereas before this treatment it had ranged between 118/78 and 144/72. The electrolyte pattern during this treatment is shown in fig 1.

Effect of Acetylsalicylic Acid—For the following six weeks he was given enough acetylsalicylic acid to keep him fairly comfortable, and he continued to work steadily although his joints were stiff and he had difficulty in moving. During this time the laboratory findings remained essentially the same as they had been at the time of the initial examination. The acetylsalicylic acid was discontinued for two weeks, and during this time the aching of the feet, legs, knees, shoulders, and hands became moderately severe. The findings from a physical examination at this time were similar to those before A.C.T.H. therapy.

Effect of Cortisone Acetate—He was given cortisone acetate 300 mg intramuscularly one day and then 100 mg daily for four days. After the first day of therapy he felt decidedly better, he slept all night had only slight pain in his joints, and had almost lost his stiffness. He continued to improve, and by the third day of therapy he could move with ease and was sleeping and eating well. The pain in his joints decreased greatly although it was not completely relieved. On the fifth day of therapy he developed pitting oedema of the feet and he weighed 8 lb more than at the start of treatment. The cortisone injections were then discontinued. There was no significant change in the other laboratory findings except that the B.P. had increased from 124/76–132/80 before treatment to 164/80–166/90 during cortisone therapy. The oedema of the ankles disappeared slowly and three weeks after the cortisone was discontinued his body-weight returned to the initial level. The electrolyte pattern during treatment with cortisone acetate is shown in fig 2.

Further Treatment—Three weeks elapsed without therapy and during this time the stiffness of the joints gradually returned and the aching became more severe but the patient went on working. At the end of this time he was given deoxycortone acetate 10 mg intramuscularly and ascorbic acid 1 g intravenously daily for four days, followed by deoxycortone acetate 10 mg alone for five days. This gave no relief. Sodium chloride was not restricted during this

period of therapy with deoxycortone acetate and ascorbic acid as it had been during the first period three months previously. He developed oedema of the hands and ankles and gained 7 lb in weight whereas previously when the salt intake was restricted while these drugs were being administered, oedema had not developed. The B.P. increased from 126/70 before therapy to 150/70 after administration of deoxycortone acetate and ascorbic acid.

After the deoxycortone acetate had been discontinued, no therapy of any kind was given for four days. By the end of this time there was intense pain in all the affected joints. The administration of cortisone acetate 300 mg intramuscularly one day and 100 mg on each of the three succeeding days again gave prompt relief. In the six weeks that have since elapsed he has had a series of six injections of A.C.T.H. 100 mg, and two weeks later another series of four injections of 50 mg each. Each time the aching and stiffness of his joints were relieved and each time they returned after therapy was discontinued. Nevertheless the severity of the pain has been relieved sufficiently to enable him to continue working regularly as a machinist.

SUMMARIES OF THE OTHER CASES

Case 2—A white housewife, aged 31, had had psoriasis for twenty-two years and severe rheumatoid arthritis for ten years. The psoriasis had appeared first on the scalp and seven years later on the chest and abdomen. The lesions had almost cleared for various periods of time the longest having been during her first pregnancy when swelling of her left thumb first developed. Gradually the joints of both hands and feet had become involved. Vitamins, hot baths and salicylates had not relieved the arthritis and the psoriasis had not been benefited by sulphonamides and various ointments. For nearly a year she had been unable to do her housework without assistance.

On examination the joints of the hands and feet were all enlarged and tender. There was moderate limitation of movement in the hands and feet and the fingers were partially flexed. Numerous psoriatic lesions on the abdomen, sacrum, lower back and upper cervical regions were elevated, red, and scaling.

Treatment—In the past year she has received A.C.T.H. 375 mg in 7 days, also cortisone 700 mg in 5 days, and 2250 mg in 36 days (total 2950 mg).

Results—Three days after beginning treatment with either A.C.T.H. or cortisone acetate there was less redness, itching, scaling, and induration of the psoriatic lesions. Within the next day the tenderness and swelling of the joints began to subside. She could use her hands and walk better than she had done for years. The skin lesions continued to subside although they did not clear completely. After each period of therapy she has been able to do all her own housework.

During the 36-day period of treatment the cortisone was given as follows: 300 mg the first day, 100 mg daily for four days, and 50 mg daily for 31 days. At the somewhat higher dosage the patient's appetite increased tremendously, she ate breakfast for the first time and consumed much more food for the other meals than she had before treatment. Even after the dose was decreased to 50 mg daily she continued to have an excellent appetite. She gained 8 lb in weight and maintained this weight for many weeks. Her good appetite persisted even after the end of therapy. There did not seem to be any abnormal distribution of body fat, and there was no oedema. After this period of therapy she became disturbed about a delayed menstrual period.

The B.P. and body weight increased slightly during therapy, but no clinical evidence of pitting oedema developed. They returned to the initial level soon after therapy was discontinued. The circulating eosinophils decreased from 102 to 0 per c.mm. by absolute count four hours after the administration of 25 mg of A.C.T.H. The corrected E.S.R. decreased from 24 mm in one hour to 15 mm in one hour in 14 days, after the administration of 875 mg of cortisone acetate.

Case 3—A white housewife aged 42 had had severe rheumatoid arthritis involving the jaws, shoulders, hands, wrists, knees, ankles and feet for seven years. At first she had occasional pain in her joints. Gradually the pains became more frequent and more severe. Eighteen months before we first saw her she had begun to have severe pain and swelling of all the affected joints. Salicylates had given only slight relief. There was severe limitation of movement in the wrists, ankles and knees. She could walk only with

each case all the urine passed in twenty-four hours was collected and measured. Frequent blood studies throughout each period included red-cell counts, differential leucocyte counts, hematocrit determinations, and erythrocyte sedimentation rates (E.S.R.). In addition, the following chemical analyses were made at short intervals: non protein nitrogen (N.P.N.), sugar, uric acid, cholesterol, serum-protein, and albumin/globulin ratio. The urinary excretion of sodium and potassium and the blood sodium and blood potassium levels were determined before, during, and after each material was administered. These analyses were done with a Perkin Elmer model 52 A photometer by the internal standard technique (Bills et al 1949).

AN ILLUSTRATIVE CASE

Case 1—A machinist aged 65, had had crippling arthritis for nine years. His father had rheumatism, his wife had had arthritis for ten years, and his only child a daughter now aged 40, had had arthritis for two years. Except for whooping-cough and influenza he had had no serious illness and he denied any allergy. He had had excellent health until 1941, when he developed pain and stiffness in his neck. These attacks lasted several days, were often associated with cold damp weather, and recurred rather frequently, but there was no tendency to spread until 1945, when pain, swelling, tenderness, and stiffness began in the hands, elbows, shoulders, knees, ankles, and feet. Soon after this the patient noticed deformities and limitation of movement in his joints, he became weak and lost his appetite. From that time he had never had a full remission of the arthritis, though on some days his joints were less painful, the disease was progressing slowly and steadily. Many types of therapy, including salicylates, had been tried, but without real benefit.

Physical examination showed a rather small, moderately well built and somewhat emaciated man obviously suffering great pain in the joints of the hands, arms, legs, and hips. It was almost impossible for him to rise from a sitting position, walk, or change his clothes.

The tone and texture of his skin were good except over the involved joints, where the subcutaneous tissue was thickened. There was a heavy growth of hair normally distributed over the body. The lymph nodes in all areas were palpable, varying in size from a few millimetres to 1.5 cm in diameter, they were firm and not tender. The lungs were resonant, a few inconstant sibilant râles were audible at the bases. The heart was normal in size, rate and rhythm, no murmurs were heard. The blood pressure (B.P.) was 150/80 mm Hg. The abdomen was scaphoid, the liver and spleen were not palpable.

There was moderate dorsal kyphosis, with slight limitation of the cervical spine in all directions. Enlargement or swelling, deformity, limitation of movement, tenderness, and weakness were present in the hands, wrists, elbows, shoulders, knees, ankles, and feet, the hands being the most severely, and the ankles and shoulders the least severely, affected. The fingers were deviated to the ulnar side and could not be completely flexed or extended. There was some general muscle atrophy, and there was extensive atrophy of the intrinsic muscles of the hands, the radial group of the fore arms, and the extensor group of the thighs. There was increased fluid about the knee joints, particularly about the anterior aspect.

Three or four firm slightly tender subcutaneous nodules were found on both the plantar and dorsal aspects of the fingers and the thumbs, the second and third fingers of both hands were particularly swollen. There were larger softer multilobular nodules over each olecranon, and firm slightly tender nodules over the upper portion of each ulna, over the heels, over the medial aspect of the first metatarsophalangeal joints and over the dorsum of three or four toes of each foot. The patient moved slowly and with difficulty from a sitting to a standing position and he walked with a wide base short steps and apparently little movement at the knees and ankles.

Laboratory Findings—The E.S.R. was 50 mm in one hour (corrected 38 mm in one hour). Examination of the blood showed N.P.N. 27 mg, sugar 68 mg, cholesterol 78 mg (esters 50 mg, free 28 mg), uric acid 1.70 mg and total protein 6.5 g per 100 ml (albumin 4.35 g, globulin 2.30 g, albumin/globulin ratio 1.90/1), red cells 4,720,000 per c.mm., white cells 6100 per c.mm. (polymorphs 78%, eosinophils

3%, lymphocytes 8%, myelocytes 11%), Hb 12.6 g per 100 ml (82%), reticulocytes 1.9%, packed cell volume 40.5%, mean corpuscular haemoglobin 27%, mean corpuscular haemoglobin concentration 31%.

Radiography showed demineralisation of the bones, particularly of the hands and feet, with narrowing of the joint spaces and obvious deformities.

Effect of Saline Solution—The patient was given 1 ml. of physiological saline solution intramuscularly twice daily for four days without relief of the stiffness and aching of the joints.

Effect of Pregnenolone—Likewise, he obtained no relief from pregnenolone acetate 300 mg by mouth daily for two weeks.

Effect of A.C.T.H.—Next, without his knowledge, he was given A.C.T.H. 15 mg intramuscularly four times daily for four days. Four hours after the first injection of A.C.T.H. he volunteered that the aching and soreness of his hands had almost disappeared, that he could open and close his hands with comparative ease, that the stiffness in his knees had disappeared, and that he had walked up four flights of stairs without difficulty. On rising in the morning after the second day of therapy he felt better than he had for three months. He threw back the bed covers without delay and got right up, whereas, before treatment with A.C.T.H., it took him five or ten minutes to get from under the bed covers and from ten to fifteen minutes to get out of bed. By this time he appeared rested, his colour was good, and he could move with ease even in full motion, and his gait was normal. He continued to feel better than he had since the onset of his illness until the third day after the injections of A.C.T.H. were discontinued, when he began to have slight pain in his joints. That night the pain woke him twice, and in the morning his hands were slightly swollen and stiff and he could not close them so easily as on the previous day. He noticed also that he had less freedom of movement. He was given injections of saline solution for four days, and at the end of this time the aching and stiffness of his joints continued though they never became so severe as they had been before A.C.T.H. therapy. He then was given acetyl salicylic acid in amounts up to gr 45 daily for four months, during which time he was moderately comfortable and able to continue working.

Effect of Deoxycortone Acetate and Ascorbic Acid—At the end of this time it was decided to give him deoxycortone

Fig 1—Effect of deoxycortone acetate on electrolyte pattern of a patient on low-sodium diet.

Treatment—Within the past year he has had A.C.T.H. 157 mg in 5 days, 200 mg in 7 days, and a single dose of 25 mg (total 412 mg) also cortisone 1650 mg in 10 days.

Results—The administration of either A.C.T.H. or cortisone acetate was followed by a dramatic improvement within 24–48 hours. On the second day of treatment he could easily rise from a sitting position unaided and could walk rapidly and without pain, and the swelling of the joints disappeared. Within a week from the start of treatment the nodules were smaller and less painful and the lymph nodes were less swollen. During the initial period of therapy he had a remarkable increase in appetite and gained weight progressively without developing any clinical evidence of oedema. His excellent appetite and weight gain continued after treatment was discontinued. His weight at the beginning of therapy was 140 lb., four months later it was 156 lb. He had no appreciable symptoms for two and a half months after treatment with A.C.T.H., and no disturbing symptoms for four months. During this time he could do the long and difficult laboratory work required of a junior student majoring in chemistry. Five months after A.C.T.H. therapy he gradually began to lose appetite and weight, and was slowed down in all his activities until he returned home for vacation, and treatment could be resumed. Despite his symptoms he completed a full year's work. During the second period of therapy when he was given cortisone he again responded promptly.

There was essentially no change in B.P. throughout therapy, and no evidence of pitting oedema. The circulating eosinophils decreased from 1046 per c.mm. to 0 by absolute count four hours after the injection of 25 mg of A.C.T.H. The corrected E.S.R. decreased from 43 mm in one hour to 11 mm in one hour in 10 days after the administration of 1650 mg cortisone acetate intramuscularly.

DISCUSSION

After the withdrawal of treatment with A.C.T.H. there was a fairly prompt diuresis with loss of oedema in the patients who developed oedema, and the electrolyte pattern returned rapidly to the pre-treatment level. In general, the response to cortisone was a little slower than to A.C.T.H., after the cortisone was discontinued, the electrolyte pattern returned to normal much more slowly, there was no great diuresis, and the loss of oedema was much slower. The pattern of symptomatic relief was essentially the same after the administration of either of these materials, it was characterised by a decrease in stiffness, an increase in range of movement at the joints, a decrease in pain and tenderness, swelling, weakness, and fatigability, and an improvement in appetite. Perhaps the earliest objective indication of a favourable response was the change in facial expression and colour. Before treatment all the patients appeared fatigued, dejected and pale. A favourable response was invariably accompanied by an alert expression and what seemed to be a vasomotor reaction manifested by an increased pinkness of face and hands. The reverse applies to a developing relapse: a pallor develops which is not related to anaemia and an appearance of fatigue is observed.

An increase in appetite and food intake invariably accompanied the beginning relief of symptoms, and in each case there was a gain in body-weight. Rounding of the face or "moon face," did not develop in any of the patients. None of them developed cutaneous striations, acne or hallucinations. None of the females developed hirsutism or amenorrhoea. Three patients developed what might be termed euphonia: they were mentally more active than usual and did not sleep well. These symptoms promptly regressed when the administration of cortisone or A.C.T.H. was discontinued.

In each patient the daily injections of deoxycortone acetate, and in five cases the daily injection of cortisone or A.C.T.H. led to pitting oedema, an increase in systolic and diastolic blood pressure, and retention of sodium in the blood and tissues when the diet was unrestricted in sodium. (Deoxycortone acetate seems to be about twenty times as effective per unit of weight as cortisone

in producing sodium retention.) When deoxycortone acetate, A.C.T.H., or cortisone therapy was discontinued, the sodium retention and the oedema disappeared, and the blood-pressure returned to the initial level. The administration of these drugs in the same amounts while the diet was low in sodium content was not followed by oedema, increase in blood pressure, or sodium retention. The symptoms were relieved after the administration of either A.C.T.H. or cortisone regardless of whether or not the sodium content of the diet was low. (Detailed chemical findings of the sodium and potassium study will be reported separately.)

There are changes in the plasma electrolyte pattern and in the urine which vary with the dosage of A.C.T.H. and cortisone, the length of time they are administered, and the patient. Our preliminary findings are in keeping with those of others in that they suggest that a negative nitrogen balance tends to develop during the administration of A.C.T.H. and cortisone. Often there is a slight increase in uric acid in the urine, an elevation of the blood sugar level, and a tendency for the serum albumin and serum-globulin levels to change toward normal. Asthenia was observed in several patients after the withdrawal of these materials.

Though we used various dosages of cortisone, our tentative recommendation for an adult is a dose of 100 mg three times a day the first day, 100 mg twice a day the second day and until there is some amelioration of symptoms, and thereafter 100 mg daily until the symptoms are fairly well under control. Then, 50 mg a day is given to determine if this amount is adequate. We prefer to administer not more than a total of 2.5 g and then to allow an interval without therapy. In the treatment of an adult with rheumatoid arthritis with A.C.T.H. we prefer to give a daily dosage of 60–100 mg divided into three or four equal doses and injected every six or eight hours until the patient shows definite improvement, which usually happens on the second or third day. Then the daily dosage can be reduced to about half. We prefer to give not more than a total of 1.5 g before allowing an interval without therapy. We are studying maintenance therapy with A.C.T.H. in one series of patients and cortisone in another series, in an attempt to find how much the necessary dosage varies from case to case.

The seven patients are partially rehabilitated. One, aged 21, attends a university, one of the men works as a machinist, and one can oversee the work in his small store. The fourth man is a retired bridge construction worker who has not worked for a number of years but can now go fishing. The three women can do their own housework. It cannot be said of any of them that they are in perfect health or that they are free from symptoms. The administration of A.C.T.H. or cortisone was always discontinued before they were entirely symptom-free; the sedimentation rate was still slightly raised, and occasional twinges of pain in some joints persisted. We worked on the theory that the changes of humoral toxicity were greatly decreased if treatment were given periodically and never for a long time. The mere fact that the patients can walk and do light work probably means that they have less muscle atrophy than they had when treatment was started. Had they not been treated, it seems likely that each of these seven patients would have been confined to bed or to a wheel-chair.

There is no evidence that the fundamental progress of rheumatoid arthritis has been cured by A.C.T.H. or cortisone therapy, nor is there any suggestion that these materials will cure the disease. There is evidence, however, that the course of the disease is favourably influenced. We are certain that none of the patients are any worse, and we are equally certain that they have obtained temporary remissions. In view of the undesir-

great difficulty and could not rise from a sitting position without aid. For over a year she had been unable to comb her hair. She spent all day doing housework that had required not more than four hours before her illness.

Treatment—Within the past year she has had A.C.T.H. 695 mg in 9 days, 64 mg in 2 days, 175 mg in 5 days, and 275 mg in 10 days (total 1209 mg). She has also had cortisone 1250 mg in 5 days, 1000 mg in 8 days, 1050 mg in 6 days, and 1850 mg in 13 days (total 5150 mg).

Results—The administration of either A.C.T.H. or cortisone acetate was followed by striking relief of pain the day after the initial dose. She could comb her hair, rise from a sitting position without help, and walk with ease. The swelling of the joints gradually subsided. After each period of therapy she has been able to do her housework in about half the time it required previously. There was a very slight increase in B.P. after treatment, and the body weight increased slightly, but there was no clinical evidence of pitting oedema. The B.P. and body weight returned to the initial level soon after therapy was discontinued. The circulating eosinophils decreased from 105 to 84 per c mm by absolute count four hours after the injection of 25 mg of A.C.T.H. The corrected E.S.R. decreased from 65 mm in one hour to 24 mm in one hour in five days, after the administration of 1250 mg of cortisone acetate intramuscularly.

Case 4—A white housewife, aged 58, had severe rheumatoid arthritis involving nearly all her joints. Transient pains in the joints had begun seven years before we saw her, and in the first five years she had had several remissions. For two years the pain and stiffness had become progressively worse, until she could not rise from a chair, turn over in bed, comb her hair, or dress herself. For six months she had been unable to wear shoes, because of the pain and swelling in her feet. Vitamins, sedatives, and salicylates had given no relief. Her feet, ankles, wrists, and elbows were so swollen that examination was difficult. For six weeks she had been unable to do her own housework.

Treatment—In the past year she has received A.C.T.H. 240 mg in 5 days, 56 mg in 2 days, 100 mg in 4 days, and a single dose of 50 mg (total 446 mg), also cortisone 325 mg in 2 days, 1000 mg in 8 days, 550 mg in 4 days, and 1050 mg in 10 days (total 3525 mg).

Results—On the second day after the administration of either A.C.T.H. or cortisone acetate she was less stiff. On the third day the swelling of the joints began to decrease, and she could dress herself, wear her shoes, and raise her hands above her head. By the seventh day she could walk with comparative ease, and her joints were not tender except to very hard pressure. Since the first period of therapy she rarely has been unable to do her own housework. There was no significant change in her B.P. after the administration of either A.C.T.H. or cortisone. Though there was a slight increase in body weight, no clinical evidence of oedema appeared. Her weight returned to normal after the medications were discontinued. The circulating eosinophils decreased from 107 to 0 per c mm by absolute count four hours after the injection of 25 mg of A.C.T.H. The corrected E.S.R. decreased from 56 mm in one hour to 27 mm in one hour in two days, after the administration of 325 mg of cortisone acetate.

Case 5—A white man, aged 64, had severe rheumatoid arthritis of the hands, wrists, elbows, shoulders, knees, ankles, and feet, and slight arthritis of the neck and hips. His illness had begun, 2-2½ years before his first visit to the clinic, with an acute onset of pain in the right shoulder, which had responded to sedation. During the next few months there had been several recurrences of pain in his right shoulder, and then the other joints mentioned had become involved with increasing severity and persistence. The symptoms included stiffness, pain, and swelling of the joints and general weakness. Eventually the intense pain and disability forced him to discontinue working as a bridge construction worker. Vitamins, liver extract, and salicylates had not given any relief. When we first saw him any movement caused severe pain. His gait was slow, deliberate, and stiff. He had difficulty in rising from a sitting position and in raising his arms. There was moderate swelling, tenderness, and limitation of movement in the hands, wrists, feet, ankles, and knees, and moderate limitation of movement in the shoulders. For two months he had spent most of his time in a wheel-chair. The E.S.R. was rapid. There was moderately severe anaemia, such that there was dyspnoea

on mild exertion. Radiography of the affected joints substantiated the clinical picture of moderately severe rheumatoid arthritis.

Treatment—In the past year he has received A.C.T.H. 240 mg in 4 days, 50 mg in 2 days, 48 mg in 2 days, 100 mg in 4 days, 50 mg (single dose), and 200 mg in 4 days (total 688 mg), also cortisone 1000 mg in 6 days, 900 mg in 7 days, 600 mg in 4 days, and 1550 mg in 10 days (total 4050 mg).

Results—Within twenty-four hours after the administration of either A.C.T.H. or cortisone acetate there was great improvement in joint function. Within forty-eight hours he could close his hands with ease and walk up and down stairs without difficulty. After each period of therapy he has not been forced to use a wheel chair. Recently he went deep-sea fishing and he has been active in cultivating his vegetable garden and in doing odd jobs about his home. He has been using pick, shovel, and rake. At present (three weeks after the end of therapy) he has little discomfort—none while at rest, but slight soreness of the feet and knees when he walks. None of the joints are swollen or tender. There is very little limitation of movement in the hands. His colour is good, the face and finger tips are pink. He has no oedema and no dyspnoea on exertion.

After the administration of either cortisone acetate or A.C.T.H. there was a slight increase in B.P., moderate pitting oedema of the feet and ankles, and a gain in body weight. On two occasions the patient has gained 20 lb in weight. The oedema which had developed during A.C.T.H. therapy subsided very rapidly, with a profuse diuresis which developed within 48 hours after the end of treatment. On the other hand, the oedema that had developed on cortisone therapy subsided slowly over a period of from ten days to two weeks and was not associated with prompt diuresis after the end of therapy. The circulating eosinophils decreased from 350 to 100 per c mm by absolute count four hours after the administration of A.C.T.H. 25 mg. The corrected E.S.R. decreased from 48 mm in one hour to 30 mm in one hour in seven days after the administration of 1000 mg of cortisone acetate.

Case 6—A white man, aged 53, had had moderately severe rheumatoid arthritis in the ankles, legs, arms, shoulders, neck, and jaws for four years. At first his symptoms had been mild and intermittent, but gradually they became more severe until for two months he was unable to work in his grocery store and some days could not walk more than a short distance. Salicylates and "vitamin shots" had given him no relief, and for the past eight months he had been able to work only part-time in his store.

On examination there was moderate swelling and limitation of movement of the ankles, wrists, and fingers.

Treatment—In the past year he has received A.C.T.H. 300 mg in 6 days, and 500 mg in 5 days (total 800 mg), also cortisone 700 mg in 7 days, and 1100 mg in 10 days (total 1800 mg).

Results—Relief of pain followed within 24-48 hours after the administration of either A.C.T.H. or cortisone acetate. Within two days he could move with ease and the swelling began to subside. On the third day of therapy the swelling disappeared. Since the initial period of therapy he has been able to supervise the work in his store.

There was a slight rise in B.P. during therapy with either cortisone acetate or A.C.T.H., which subsided promptly when treatment was discontinued. Although his weight increased slightly, there was no clinical evidence of pitting oedema. His B.P. and weight returned to the initial level soon after therapy was discontinued. The circulating eosinophils by absolute count decreased from 282 to 81 per c mm four hours after the administration of A.C.T.H. 25 mg intramuscularly. The corrected E.S.R. decreased from 26 mm in one hour to 19 mm in one hour in fifteen days after the administration of cortisone acetate 500 mg intramuscularly.

Case 7—A white university student, aged 21, had had severe rheumatoid arthritis of nearly all the joints for two and a half years. All the joints had been involved at one time or another. When we first saw him he was having severe pain in both shoulders, both knees, the left wrist, and the fingers of both hands. "Gold shots" and salicylates had not relieved the pain. There were tender painful nodules over the extensor surfaces just below both elbows and both heels. The lymph glands were moderately enlarged and became painful each time there was an exacerbation of the arthritis.

but their sera were invariably negative. Hydrocephalus and convulsions may be common features of congenital toxoplasmosis, but no positive serum was obtained from a child in whom these were the only signs suggesting the disease. A few weakly positive tests were obtained in a group of children with psychomotor retardation, but these were not confirmed by further investigation.

Among the normal controls all the positive sera were from adults, and, excluding the samples from children, this series suggests that about 5% of normal adults have had previous contact with the parasite. The figure is rather higher than that previously found in this country (Macdonald 1949, Cathie and Dudgeon 1949). Among the 100 normal children under ten years there was no positive serum, and though the number examined is small this suggests that symptomless infection is not often acquired in early childhood.

The finding that 5% of "normal" adults have evidence of symptomless infection has two implications in assessing the diagnostic value of laboratory tests. A positive serological test does not necessarily confirm the diagnosis of toxoplasmosis in an adult in whom the congenital form of the disease is suspected on clinical grounds. Of 10 adult epileptic patients (not included in table I), 2 gave positive complement-fixation tests, but their contact with toxoplasma may have been fortuitous. Similarly we did not obtain definitely positive results in several samples of serum from adults with chorio-rebitis. We must know more about the persistence of

TABLE II—TOXOPLASMA COMPLEMENT FIXING ANTIBODY IN INFECTED CHILDREN AND THEIR MOTHERS

antibody after infection before such tests can be relied on in adults. The occurrence of symptomless infection in adults also makes it impossible to diagnose a child's illness from the serological findings in the mother's blood only. Though a high titre of maternal antibody may suggest recent infection, we cannot safely deduce from it that the child had congenital toxoplasmosis, even when this is suspected clinically.

ANTIBODY TITRES IN MOTHER AND CHILD

From what has been said it is clear that samples of blood from both mother and child are needed to confirm a clinical diagnosis. Other workers have compared the titre of antibody in the mother's and in the child's serum, and if the cases are infected in utero one might expect the antibody level of the affected child to fall with increasing age. Table II shows no apparent relation between the titre of antibody in 10 mothers and their children and little to suggest that the infant's age is a reliable guide to the amount of complement fixing antibody in its serum. Moreover, it will be seen from table II that the mothers of the last 3 cases listed still showed antibody in the blood several years after they had presumably transmitted infection to their unborn children.

In 3 instances re-examination at eight, ten and twelve months of serum from mothers who had given birth to infected children some two years previously showed no detectable loss of complement fixing antibody during

Infants	53	8	2	3	2	—	1

these periods. Whether the persistence of antibody in the mother means that parasites are still being carried and that there is thus a continuing stimulus to antibody formation is not known.

TRANSFER OF MATERNAL ANTIBODY

Sabin and Feldman (1949a) have recently investigated the dye test and complement fixing toxoplasma antibodies in 3 mothers who had given birth first to a child with toxoplasmosis and then to a normal child. They found that both types of antibody were transmitted to the normal infants and that the transferred antibodies had almost disappeared after 4 or 5 months.

During the examination of sera from 53 mothers and from their newborn infants who had some congenital abnormality it was learned that only 1 child had clinical signs strongly suggestive of toxoplasmosis and it died soon after birth. The cord blood in this case contained antibody but maternal was not available for attempts to demonstrate the parasite. The mother's blood gave positive complement fixing, dye, and neutralisation tests. However, a number of mothers whose infants were normal, and also some mothers of infants with congenital defects such as spina bifida and anencephaly, had antibody in their sera, and positive tests were also obtained from samples of cord blood from the infants.

Table III shows that of the sera from 53 mothers of infants with congenital defects 9 gave positive fixation at a serum dilution of 1/10 or over. This is a rather higher proportion of positives than was found in normal adults and it naturally suggested that in the sera of recently delivered women there was some non specific fixation of complement. However, all the positive samples in table III also gave positive dye and egg neutralisation tests, and the reaction appeared to be due to specific antibody. Samples of cord blood gave very similar results, and table III suggests that there is an almost quantitative transfer of antibody from the maternal to the foetal circulation, this was true whether complement-fixing or neutralising antibody was estimated.

In 5 of these cases giving positive tests second samples of sera were obtained from both mother and infant and these were then tested in parallel with the first sera, using the same antigen in the case of the complement-fixation technique. The interval between the collection of the first and second samples of blood varied from four to nine months and in all cases the mother's blood gave almost identical results in the two tests. However, in the second samples of all the infants' sera the titre of antibody as measured by complement fixation was less than 1/5, the toxoplasma neutralising power on eggs had disappeared and the dye test titres were very much reduced. There was, in effect the expected loss of passively transferred antibody in the children and there was also no clinical evidence that they had acquired the disease.

It seems clear, therefore that maternal antibody can be transferred to the foetal circulation and that this occurs without any simultaneous transfer of infection. It may be that the mother who already possesses antibody in her blood does not infect her foetus and the protective effect of anti serum which can be demonstrated on the chorio allantois probably also operates in the human body. If this is so it suggests that only a woman who

able effects of long continued treatment with either cortisone or ACTH, and the minimal undesirable effects observed in our patients treated as they were, it seems probable that therapy with these hormones will develop on the lines we have tried—i.e., patients will not be treated continuously but at each relapse will receive the minimum amount of hormones needed to establish a remission. Possibly ACTH and cortisone should be used alternately.

SUMMARY AND CONCLUSIONS

Seven patients with rheumatoid arthritis were treated at intervals over a period of twelve months with pituitary ACTH and synthetic cortisone acetate. In each case the symptoms improved after the injection of adequate amounts of either of these materials. In contrast, pregnenolone acetate, deoxycortone acetate and ascorbic acid, acetylsalicylic acid, and placebos produced no relief.

After the injections of cortisone or ACTH were discontinued the symptoms gradually returned. The longest period of relief following a series of injections was four and a half months. After each period of either cortisone or ACTH therapy the relief of symptoms was as great as that which followed the initial period, suggesting that the effectiveness of these hormones does not diminish in a year.

INCIDENCE OF TOXOPLASMA INFECTION IN NORTH-WEST ENGLAND*

TRANSMISSION OF ANTIBODY FROM MOTHER TO FETUS

ALEXANDER MACDONALD

M.A., M.D. Aberd.

READER IN BACTERIOLOGY, UNIVERSITY OF LIVERPOOL

SINCE the first reports of congenital toxoplasmosis in Britain by Jacoby and Sagorin (1948) and by Farquhar and Turner (1949) only a few further cases have been described and we still know little about the incidence or distribution of the disease in this country. Complement fixing and neutralising antibodies are present in the serum of some apparently healthy people (Macdonald 1949, Cathie and Dudgeon 1949), and symptomless infection may not be uncommon, at least in adults. Clinicians recognise a number of signs which suggest congenital toxoplasmosis, but it is clear that, by themselves, these signs are insufficient for diagnosis. Nevertheless, it is important to try to circumscribe the range of clinical manifestations which calls for laboratory investigation and to obtain some guidance on the incidence of the infection. This note is chiefly concerned with the results of tests on samples of serum from infants and mothers submitted by clinicians, mainly in north-west England. The findings will also be discussed in relation to the transfer of maternal antibody to the fetus.

LABORATORY METHODS

For the detection of antibody in sera the complement fixation test, with soluble egg antigen derived from

infected chorio allantoic membranes, was used as a routine. The technique was similar to that previously described (Macdonald 1949), but in preparing the antigen final centrifugation was carried out at 9000 r.p.m. for an hour. A serum which fixed complement with this toxoplasma antigen at a dilution of 1/10 or higher was considered positive, at 1/5 the result was regarded as doubtful.

Feldman and Sabin's dye test and the neutralisation test on the chorio allantois were also used for the detection of antibody in all doubtful and positive cases but in only a proportion of cases which gave negative complement fixation. Cathie and Dudgeon's modification of the dye test was used, and the neutralisation test in eggs was done with unheated serum which was kept frozen until required. Since many workers consider that the dye test is the most sensitive method, more positive results might well have been obtained if this test had been applied to all specimens. Sabin (1949), however, takes the view that with egg antigen the complement fixation method by itself can supply the laboratory diagnosis in most cases of congenital toxoplasmosis.

COMPARISON OF CLINICAL AND LABORATORY FINDINGS

It is assumed that antibody in a patient's serum which reacts with toxoplasma antigen is the result of specific contact with that parasite, since no organism related antigenically to toxoplasma has yet been described. Clinical signs in an infective process are necessarily variable, but in correlating tests for toxoplasma antibody with the clinical picture we have accepted as cases of toxoplasmosis only those children who had both chorio retinitis and cerebral calcification. Some such selection was necessary because of the variety of pathological conditions which can give rise to one or other of the recognised signs of toxoplasmosis, and the arbitrary choice of clinical manifestations was influenced by Sabin's view that nine out of ten cases of the disease have both these signs. Most of the cases considered doubtful on clinical grounds were in infants or young children who did not qualify for the first group but had some other signs of congenital toxoplasmosis. The group of "normal" controls is composite: 150 sera from blood donors, 100 from children under ten years, and the remainder specimens of adult serum sent for tests other than for toxoplasmosis.

There is good agreement between the clinical diagnosis and the results of laboratory tests in the first group of children in table 1. Of the 2 patients who satisfied the clinical requirements but gave negative complement fixation, one gave a titre of 1/64 by the dye test, which by itself was not thought significant, while the other was negative by all tests.

In the group of doubtful cases only 6 out of 88 sera gave positive complement fixation, 4 were confidently diagnosed on clinical grounds and had positive dye and neutralisation tests, though they did not have both chorio retinitis and cerebral calcification, and in 2 others the dye and egg neutralisation tests were doubtful or negative. All other children with hydrocephalus, chorio retinitis, or convulsions, or combinations of these, gave negative serological tests. This doubtful group included some members of the same families with chorio retinitis,

TABLE 1—CORRELATION BETWEEN CLINICAL AND LABORATORY DIAGNOSIS

* Based on a paper read at the Brighton meeting of the Association of Clinical Pathologists, January, 1950.

if their sera were invariably negative. Hydrocephalus and convulsions may be common features of congenital toxoplasmosis, but no positive serum was obtained from a child in whom these were the only signs suggesting the disease. A few weakly positive tests were obtained in a group of children with psychomotor retardation, but these were not confirmed by further investigation.

Among the normal controls all the positive sera were from adults, and, excluding the samples from children, this series suggests that about 5% of normal adults have had previous contact with the parasite. The figure is rather higher than that previously found in this country (Macdonald 1949, Cathie and Dudgeon 1949) among the 100 normal children under ten years there was no positive serum, and though the number examined is small this suggests that symptomless infection is not often acquired in early childhood.

The finding that 5% of "normal" adults have evidence of symptomless infection has two implications in assessing the diagnostic value of laboratory tests. A positive serological test does not necessarily confirm the diagnosis of toxoplasmosis in an adult in whom the congenital form of the disease is suspected on clinical grounds. Of 10 adult epileptic patients (not included in table 1), 2 gave positive complement fixation tests, but their contact with toxoplasma may have been fortuitous. Similarly we did not obtain definitely positive results in several samples of serum from adults with choroiditis. We must know more about the persistence of

TABLE II—TOXOPLASMA COMPLEMENT FIXING ANTIBODY IN INFECTED CHILDREN AND THEIR MOTHERS

antibody after infection before such tests can be relied on in adults. The occurrence of symptomless infection in adults also makes it impossible to diagnose a child's illness from the serological findings in the mother's blood only. Though a high titre of maternal antibody may suggest recent infection, we cannot safely deduce from it that the child had congenital toxoplasmosis, even when this is suspected clinically.

ANTIBODY TITRES IN MOTHER AND CHILD

From what has been said it is clear that samples of blood from both mother and child are needed to confirm a clinical diagnosis. Other workers have compared the titre of antibody in the mother's and in the child's serum, and if the cases are infected in utero one might expect the antibody level of the affected child to fall with increasing age. Table II shows no apparent relation between the titre of antibody in 10 mothers and their children and little to suggest that the infant's age is a reliable guide to the amount of complement-fixing antibody in its serum. Moreover, it will be seen from table II that the mothers of the last 3 cases listed still showed antibody in the blood several years after they had presumably transmitted infection to their unborn children.

In 3 instances re-examination at eight, ten, and twelve months of serum from mothers who had given birth to infected children some two years previously showed no detectable loss of complement-fixing antibody during

these periods. Whether the persistence of antibody in the mother means that parasites are still being carried and that there is thus a continuing stimulus to antibody formation is not known.

TRANSFER OF MATERNAL ANTIBODY

Sabin and Feldman (1949a) have recently investigated the dye test and complement fixing toxoplasma antibodies in 3 mothers who had given birth first to a child with toxoplasmosis and then to a normal child. They found that both types of antibody were transmitted to the normal infants and that the transferred antibodies had almost disappeared after 4 or 5 months.

During the examination of sera from 53 mothers and from their newborn infants who had some congenital abnormality it was learned that only 1 child had clinical signs strongly suggestive of toxoplasmosis and it died soon after birth. The cord blood in this case contained antibody but material was not available for attempts to demonstrate the parasite. The mother's blood gave positive complement-fixing, dye, and neutralisation tests. However, a number of mothers whose infants were normal, and also some mothers of infants with congenital defects such as spina bifida and anencephaly, had antibody in their sera, and positive tests were also obtained from samples of cord blood from the infants.

Table III shows that of the sera from 53 mothers of infants with congenital defects 9 gave positive fixation at a serum dilution of 1/10 or over. This is a rather higher proportion of positives than was found in normal adults and it naturally suggested that in the sera of recently delivered women there was some non-specific fixation of complement. However, all the positive samples in table III also gave positive dye and egg neutralisation tests, and the reaction appeared to be due to specific antibody. Samples of cord blood gave very similar results and table III suggests that there is an almost quantitative transfer of antibody from the maternal to the foetal circulation, this was true whether complement-fixing or neutralising antibody was estimated.

In 5 of these cases giving positive tests second samples of sera were obtained from both mother and infant and these were then tested in parallel with the first sera, using the same antigen in the case of the complement-fixation technique. The interval between the collection of the first and second samples of blood varied from four to nine months and in all cases the mother's blood gave almost identical results in the two tests. However, in the second samples of all the infants sera the titre of antibody as measured by complement-fixation was less than 1/5, the toxoplasma-neutralising power on eggs had disappeared and the dye test titres were very much reduced. There was in effect, the expected loss of passively transferred antibody in the children and there was also no clinical evidence that they had acquired the disease.

It seems clear therefore that maternal antibody can be transferred to the foetal circulation and that this occurs without any simultaneous transfer of infection. It may be that the mother who already possesses antibody in her blood does not infect her foetus, and the protective effect of anti-serum which can be demonstrated on the chorio allantois probably also operates in the human body. If this is so it suggests that only a woman who

acquires her infection during pregnancy is likely to pass on the disease to her child

DISCUSSION

The serological tests indicate that congenital toxoplasmosis is rather more prevalent in north-west England than had been thought, but it is apparently not a common cause of congenital abnormality. The specimens considered here were sent by clinicians particularly interested in the disease and are not a random sample of sera from abnormal infants. On the other hand, many samples were received from infants who did not have the two characteristic signs of the disease—chorio retinitis and cerebral calcification. There are obvious dangers in demanding a particular clinical picture when considering which signs and symptoms in a child call for laboratory investigation. Moreover, it is well known that other pathological processes may give rise to much the same clinical manifestations as toxoplasmosis. Sabin's view that most children with congenital toxoplasmosis have both chorioretinitis and cerebral calcification was useful in indicating which specimens were likely to give positive serological tests. Hydrocephalus, convulsions, and psychomotor retardation have not, by themselves, been of value in this way, nor has chorio retinitis without cerebral calcification. When the clinical diagnosis was made on both chorioretinitis and cerebral calcification, 10 out of 12 sera gave confirmatory positive serological tests, whereas of the 88 sera from clinically "doubtful" cases, where both these signs were not present, only 6 gave a positive complement fixation test, and on further investigation 2 of the 6 were probably not toxoplasmosis.

A question often asked is whether a mother who has had one child with toxoplasmosis is likely to infect her subsequent children. A related problem is whether, when several members of the same family have a suggestive congenital defect, such as chorioretinitis, it is worth while examining their sera for toxoplasma infection. In several such families our tests have been invariably negative. Sabin and Feldman (1949b) and other experienced workers say that when a mother has one child with congenital toxoplasmosis her subsequent children are likely to be normal. This would support the view already expressed, that if a mother's serum contains antibody, particularly neutralising antibody, her foetus will be protected from infection. One might expect neutralising antibody to operate protectively on both sides of the placental barrier, but immunological considerations may not be the only ones involved. We do not know where or for how long the mother harbours the parasite, though it seems likely that she will transmit the infection to the foetus through her placenta only before she develops antibody—that is, only for a short time after she acquires her infection. This view might explain the low incidence of congenital toxoplasmosis in a community with a high incidence of latent infection in adults.

SUMMARY

Out of 12 children who had both chorioretinitis and cerebral calcification 10 gave positive serological tests for toxoplasmosis, whereas out of 88 children having various congenital defects but not these two signs only 4 were found to have positive sera.

Of 250 samples of serum from "normal" adults in north west England 13 gave positive complement fixation tests with toxoplasma antigen. Such symptomless infection must be kept in mind when interpreting laboratory results.

Complement fixing and neutralising antibodies are transmitted from the mother to her foetus, and it is thought that infection crosses the placenta only if the mother has been infected so recently that her antibodies have not yet developed.

CONGENITAL TOXOPLASMOSIS

REPORT OF TWO CASES IN TWINS

H G FARQUHAR

B.M. Oxfrd, M.R.C.P., D.C.H.

ASSISTANT PHYSICIAN, ROYAL LIVERPOOL CHILDREN'S HOSPITAL

With illustrations on plate

Two cases of congenital toxoplasmosis in the Liverpool district have already been described (Farquhar and Turner 1949), it was then suggested that this disease might be recognised with increasing frequency in the British Isles, and in fact seven other British cases have been recorded (Jacoby and Sagorin 1948, Wilson and Forest Smith 1949, Ridley 1949, Nutt 1949, Hutchison 1949, Wyllie and Fisher 1950). The two cases reported here occurred in twins.

CASE RECORD

A girl, aged 8 months, attended the outpatient department of the Royal Liverpool Children's Hospital with hydrocephalus for investigation. She was the first of twins prematurely born at the 34th week of pregnancy. Her birth weight had been 4 lb 2 oz, and that of her brother 4 lb. The birth had been normal, but the patient had had some neonatal pallor but no cyanosis or jaundice. The mother's health during this, her first pregnancy, had been excellent, and she had had no cough, rash, or fever.

The family was a healthy one. The mother, aged 26, had had scarlet fever at the age of 4 years, bronchopneumonia at the age of 7 years, and mumps at the age of 9 years. At the age of 19 she had had an illness diagnosed as anaemia and asthma which had required medical attention for three months, during which she had lost 3 st in weight. Clinical examination of the chest at that time was said to have revealed no abnormality, but no other record of this illness could be obtained. The father, aged 27, had had measles as a child and suffered from recurring blepharitis. Save for this he had always been healthy.

The mother had come into fairly regular contact with two dogs and two cats during her pregnancy. The house was free from mice and there were no birds in it, but the mother had worked during the first six months of her pregnancy in a factory where there were many mice.

Shortly after the patient's birth it was noticed that her right eye remained closed, and when it gradually opened the eye was seen to be smaller than the left. For the second and third months of life feeding was difficult, but with encouragement a steady weight gain was obtained. When the patient was 5 months old her mother noticed the sudden appearance of a swelling in the region of the anterior fontanelle and within two to three weeks the whole head began to enlarge rapidly. Before this the mother had remarked on the smallness of the child's head compared with that of her twin, but it rapidly became much the larger of the two. The mother suspected that the child was blind in the right eye, though she thought there was some vision in the left eye, and nystagmoid movements had been observed in both eyes. The head was not held up normally like that of her twin, and she made no attempt to sit up. There had been no convulsions or loss of consciousness.

Fig. 1.—Right-sided microphthalmos and enophthalmos in girl with toxoplasmosis.

Fig 2—Same girl as in fig 1 showing anterior fontanelle tense frontal bones prominent, and apparent downward displacement of eyes.

On examination the child weighed 16 lb. She lay on her back, taking no notice of her surroundings, with wide searching nystagmoid movements of the eyes. She often tried to raise her head off the bed but could not keep it raised. There was a right-sided microphthalmos and enophthalmos (fig 1). The skull circumference was $18\frac{1}{2}$ in. The anterior fontanelle was tense; the frontal bones were prominent, and there was a suggestion of downward displacement of the eyes (fig 2). The right cornea was 6.5 mm. in diameter, the pupil was contracted and unresponsive to light and no red reflex could be obtained. The anterior chamber was shallow but no further details could be made out, because the posterior chamber was filled with a greyish green mass obstructing the view of the fundus. The left cornea was 8 mm. in diameter. The anterior chamber was again shallow, and there were a few posterior synechiae. There were fine lental and vitreous opacities, and an area of choroidoretinal degeneration was seen in the superior temporal region. No other abnormalities were found in the cranial nerves. The hearing could not be tested accurately, but the child turned her head to a spoken voice. The arms and legs were spastic, the tendon reflexes brisk, and the plantar reflexes extensor. It was obvious that there was gross mental retardation. Examination of the other systems was essentially negative. There was no enlargement of the liver or spleen. There was no abnormal enlargement of the lymph glands, and the chest and heart were clinically normal.

Investigations.—For toxoplasma antibodies see the accompanying table. Ventricular fluid was normal microscopically and biochemically. Intraperitoneal and intracerebral injection of it into mice did not lead to infection. A blood-count showed Hb 70% red cells 4,200,000 and white cells 7000 per c.mm. (differential count normal).

Radiography of the skull showed fine calcification anterior to and above the sella turcica (fig 3 on plate). Arteriovenography (fig 4 on plate) showed gross internal hydrocephalus. Radiography of the chest was normal.

INVESTIGATION OF TWIN BROTHER

Development in the girl's twin brother was entirely normal. At 8 months he weighed 19 lb and could pull himself to his feet. Clinical examination was entirely negative except that both fundi showed very superficial atrophy in the perimacular region and a fine pigmentary deposit diffusely spread over both retinæ. Radiography of the skull and chest showed no abnormality. (For toxoplasma antibodies see the table.)

INVESTIGATION OF FATHER AND MOTHER

No clinical examination was made of the parents except of their optic fundi which were normal. Radiograms of the chests of both parents were normal. The mother's blood Wassermann reaction was negative. (For toxoplasma antibodies see the table.)

DISCUSSION

The published work on congenital toxoplasmosis has been summarised by Callahan et al. (1946), Schwartzman et al. (1948), Frenkel (1949), Wille and Fisher (1950) and others. Cross (1947) has given an excellent and detailed account of the morphology of the causal organism,

and Kean and Grocott (1948) have described the necropsy findings.

In the present cases the girl exhibited the now well known tetralogy of congenital toxoplasmosis—i.e., cerebral calcification, hydrocephalus, chorioretinitis, and positive serological tests for toxoplasma antibodies. As in most of the cases so far reported the causal parasite was not isolated. Hydrocephalus, chorioretinitis, microphthalmos, and mental retardation have all been found in infants believed not to have toxoplasmosis and having negative serological tests for toxoplasma antibodies, in such cases cerebral calcification is rare, occurring in only 5%.

In patients with positive serological reactions and these clinical manifestations cerebral calcification has been present in 90% of cases (Sabin and Feldman 1949a). Greater emphasis is therefore now laid on the finding of cerebral calcification in the diagnosis of toxoplasmosis, and its association with the typical clinical findings and positive serological tests is highly suggestive. The diagnostic tests and their significance have been fully described by Sabin and Feldman (1948), Warren and Russ (1948), and Macdonald (1949), and the pathogenesis, diagnosis, and treatment by Frenkel (1949).

Toxoplasmosis has been described in monozygotic twins by Zuelzer (1944) and Heath and Zuelzer (1945) (the same cases) and by Abbott and Camp (1947), but the latter did not consider the diagnosis proved, and in monozygotic twins by Bamatter (1947).

The boy's case reported here is of particular interest. The high titre of antibody found could in theory be explained in two ways: either it is due to antibody transmitted from the mother to the child in utero, in

RESULTS OF COMPLEMENT FIXATION AND NEUTRALISATION TESTS FOR TOXOPLASMOSIS

Test	Dye test	Complement-fixation test	Neutralisation test on chorio-allantoic membrane
Girl	1/512	1/40	+
Boy	1/512	1/40	+
Mother	1/256	1/20	+
Father	Neg	Neg	Neg
Cat	Neg	Neg	Neg
Dog	†	Anticomplementary	

the absence of any disease in the child, or the child is infected. The fact that the titre is higher in the child than in his mother seems to argue against the former hypothesis, which becomes the more improbable in the light of recent work which has demonstrated the short persistence of these antibodies in the serum of an uninfected child of an infected mother. Thus complement-fixation antibodies may be absent at the age of $4\frac{1}{2}$ months, and neutralising antibodies as demonstrated by the dye test can only be demonstrated in minute amounts in undiluted serum or at the most in half-strength serum at the age of 9 months (Sabin and Feldman 1949b).

It therefore seems probable that the boy is infected. If so it is difficult to know what significance to ascribe to the ophthalmological findings. These were very mild, and, though they were considered to be outside the range of the normal, it would be difficult to attribute them to the action of the toxoplasma organism, though this possibility cannot be entirely excluded, and their perimacular distribution might be considered suggestive. If this child is infected it is necessary to assume either that fewer parasites entered his blood than that of his twin, or that his resistance to the disease was greater. A more remote possibility is that he was infected by his mother's milk. If this is true it must have occurred in the first week of life, for after this time breast-feeding was abandoned.

SUMMARY

In binocular twins the girl had typical toxoplasmosis, with cerebral calcification, hydrocephalus, chorioretinitis, and toxoplasma antibodies in her serum

Her twin brother had similar antibodies but no clinical signs of the disease except mild ocular abnormalities. Since the mother's titre of antibodies was lower than his, and he was 8 months old, he was probably infected with toxoplasmosis and had not acquired his antibodies merely by transmission from his mother

I wish to thank Dr R W Brookfield for his kindness in letting me see these children, Prof N B Capon for his valuable criticism in the preparation of this paper, Dr N Walker for the radiological reports, Dr A Macdonald for the serological investigations, Mr J A. McCann for the ophthalmological findings, and Dr DeChenu for his help in investigating the home environment and obtaining the animal specimens

TOXOPLASMOSIS

COMPLICATED BY CHICKENPOX AND SMALLPOX

REPORT OF A CASE

IAN D RILEY

GAVIN C ARNEIL

M D Leeds, M R C P, D C H

M D Glasg, F R F P S

OF THE PEDIATRIC DEPARTMENT, STOBHILL HOSPITAL, GLASGOW

SINCE toxoplasma infection in man was first recorded by Wolf et al (1939a and b) it has been recognised in many countries. Six cases have been reported in England and two in Scotland (Jacoby and Sagorin 1948, Farquhar and Turner 1949, Hutchison 1949, Nutt 1949, Ridley 1949, Wyllie et al 1950), all being of the congenital type secondary to infection in the mother. A further case of infection in mother and child is reported below

CASE RECORD

A girl, aged 9 months, was admitted on Jan. 20, 1950, with convulsions of a few hours duration. Her mother and father, both aged 23, were interviewed and appeared to be healthy. Neither had had any unusual or unexplained illness. They had been married 3 years and had one other child, a healthy boy aged 2½ years. The retinae of the baby's mother and brother were normal, and the mother's Wassermann and Kahn reactions were negative.

The mother's health had been good during this last pregnancy apart from mild morning sickness at 3 months, and the baby had been born spontaneously but six weeks prematurely, her birth weight being just over 4 lb. Otherwise the baby had seemed normal, except for a squint, and she had eagerly taken her feeds of boiled cow's milk. At the age of 6 weeks she had had a

febrile illness with a maculopapular rash, thought to be measles.

On admission the baby had repeated convulsions, consisting of rapid generalised twitches of the whole body. These subsided a few hours after the administration of chloral, and did not return. She was small and active, tried to sit up in bed, followed a light well with her eyes, and seemed to be of normal intelligence. Her skull was asymmetrical, the left side being the smaller, and measured 15 in. in circumference (normal average for her age 18 in.). The anterior fontanelle had closed prematurely. All the tendon reflexes were brisk, the abdominal reflexes were present, and both plantar responses were extensor. All four limbs were spastic, but no clonus was elicited. There was a palsy of the sixth cranial nerve on the left side. The pupils were equal and central and reacted to light. The spleen was not palpable, and no lymphadenopathy was found. The left eye showed microphthalmos, old iritis, and chorioretinitis. In the right eye a large patch of choroiditis was visible in the region of the macula, with gross pigmentary disturbance more peripherally.

Investigations.—Blood examination on Jan. 20 showed red cells 4,150,000 per c mm., Hb 10.5 g per 100 ml., and white cells 7000 per c mm. (eosinophils 550 per c mm.), no abnormality of platelets, erythrocytes, or granular, mononuclear, or lymphocyte series. Lumbar puncture on Feb. 27 produced slightly turbid cerebrospinal fluid, containing 100 lymphocytes per c mm. and an increased amount of globulin. A Pandy test was positive. Blood Wassermann and Kahn tests on Feb. 22 were negative, and a Mantoux test with 1/1000 Old Tuberculin on Jan. 22 was also negative.

Radiography of the skull on Jan. 28 showed small areas of calcification scattered diffusely throughout the brain (see figure).

Serological Tests for Toxoplasmosis.—Cytoplasm modifying dye test positive at 1/256, rabbit skin neutralising test gave neutralisation of 100 skin test doses (Prof C P Beattie). Dye test titration positive at 1 in 250 (Prof Sven Gard). These tests were performed on mother and child with identical quantitative results, indicating recent or active infection.

Progress.—The child remained well and was afebrile, gaining weight steadily, until March 14 when she developed chickenpox. She was transferred to a fever hospital and there came in contact with an Indian seaman, later found to have smallpox. The baby was then transferred on March 27 to a smallpox hospital, and on March 31 she became pyrexial and developed a steadily progressive maculopapular and then pustular rash on her face, limbs, and palate. Scrapings of these lesions were later reported positive for smallpox. On April 3 the rash became more profuse and petechial. The smallpox appeared to be modified in severity, though the child had not been vaccinated before exposure to the infection, but she died on April 3. No necropsy was done.

DISCUSSION

It has been known for forty years that toxoplasma is parasitic on many animals, but it was not recognised to be a cause of disease in man until 1939. Cases previously reported—e.g., that of Wolf and Cowen (1937)—were then correctly diagnosed in retrospect.

Five types of infection are described (*Lancet* 1949): (1) a symptomless form in adults, detected either sero

Areas of calcification scattered diffusely throughout brain

logically or by the birth of an infected infant, (2) encephalitis in older children, (3) acute illness with a rash, resembling measles, in adults, (4) chronic encephalitis in adults, and (5) an infection acquired in utero. The organism has a predilection for the eye and the brain and has often been obtained from these sites. The clinical and pathological picture (see Binkhorst 1948) varies according to the site and extent of the lesions. In the congenital form the four most constant clinical features are deformity of the skull, convulsions, choroidoretinitis, and intracranial calcification. The diagnosis is most satisfactorily established by isolation of the organism, but this is not always possible. The serological tests described by Sabin (1942) and Sabin and Feldman (1948) provide a reliable proof of active or recent infection.

The present case presents several of the features described in the congenital type: (1) a maculopapular eruption with a febrile illness in the neonatal period, (2) microcephaly with asymmetry of the skull and premature synostosis, (3) bilateral choroidoretinitis with pigmentary derangement, left sided microphthalmos, sixth nerve palsy, and iritis, (4) convulsions, (5) scattered areas of calcification within the cranial cavity, and (6) positive serological findings. The lymphocytic pleocytosis in the cerebrospinal fluid and the well marked absolute eosinophilia in the blood suggested that the infection was active. Thus the child had the congenital form of toxoplasmosis (type 4) and her mother the symptomless infection (type 1).

We wish to thank Prof Sven Gard, of Stockholm, and Professor Beattie, of Sheffield, for doing the serological tests, Dr Spence Meighan for examining the optic fundi, and Dr M. A. Foulis for his report on the course of the child's smallpox infection in Robroyston Hospital.

SIMPLIFIED PROCEDURE FOR DETERMINING THE RENAL CLEARANCE OF INULIN AND DIODONE

O. OLBRICH

M. H. FERGUSON

Ph.D. Edin., F.R.C.P.E.

Ph.D. Edin., B.Sc. Manitoba

J. S. ROBSON

C. P. STEWART

M.D. Edin., M.R.C.P.E.

M.Sc. Durh., Ph.D. Edin.

From the Clinical Laboratory, Royal Infirmary, Edinburgh

THE main reason why measurement of the discrete functions of the kidney has not become a routine procedure is that the clearance technique originally described by Smith et al. (1938) requires continuous infusion of the test substance and catheterisation of the patient. Recently we have devised simplified methods for estimating the rate of glomerular filtration, as measured by the renal clearance of inulin (C_{in}), the tubular excretory mass as measured by the maximal capacity to excrete diodone (T_{md}), and the effective renal plasma flow, as measured by the diodone clearance (C_p). Only one intravenous injection is used and catheterisation is seldom necessary. The derivation of the formulæ

employed is given in our original communications (Robson et al. 1949a and b) where the claims of Smith and his colleagues with regard to the renal treatment of these substances have been accepted. In this paper we present the details of our technique.

All the procedures involve (1) a single injection of inulin and/or diodone, in accurately measured amount, (2) the collection of two samples of urine after intervals sufficiently long to obviate, as a rule, the need for catheterisation, and (3) the sampling of venous blood immediately before the urine is collected. The subject should have fasted from the previous evening and should be recumbent during the investigation. Water is given freely by mouth.

RENAL CLEARANCE OF INULIN

Preparation and Injection of Inulin Solution

Inulin (Kerfoot's pure bacteriological) is dissolved in sterile saline with the aid of heat to make an approximately 10% (w/v) solution, and after partial cooling the solution is passed through a sterile Seitz filter. Inulin crystallises from the sterile filtrate on cooling but is readily redissolved by warming, after which it is re-cooled to 30–35°C for injection. The inulin content of each batch of solution is determined chemically.

A sample of venous blood (for control analysis) is withdrawn from the subject and an accurately measured volume of the inulin solution containing 100–120 mg of inulin per kg body weight, is injected intravenously (a 'Record' syringe of 100 ml capacity is convenient), the injection taking 2–5 minutes. The time is noted when the injection begins and ends.

With this technique no evidence of toxicity has been observed.

Blood and Urine Collection

At two carefully noted times, about 30 and 100 minutes after the midpoint of the injection, urine is collected, the bladder being emptied as completely as possible. Since it is necessary to know only the total amount of inulin excreted, there is no need for the subject to empty the bladder before the injection. On the contrary a full bladder at that time will increase the accuracy of the first urine collection. 30 minutes later. At, or immediately before, these urine collections, venous blood is withdrawn (10 ml, oxalated).

Chemical Analysis

Inulin is determined in the plasma from the three blood samples and in the two urine samples, as well as in a sample of the inulin solution used for injection. The method used in our own determination was that of Steinutz (1938) as modified by S. W. Cole (unpublished), in which inulin is hydrolysed and the resulting levulose is determined by its colour reaction with resorcinol. For this particular method the plasma may be diluted to 2 or 3 times its volume with water and the urine to 200 times its volume with the object of producing, in the material actually analysed, an inulin concentration of about 20 mg per 100 ml. The pre-injection plasma provides a 'blank' correction, usually of the order of 1 mg per 100 ml plasma.

Calculation

The weight of inulin injected minus the weight of inulin in the urine passed at the first collection gives the weight of inulin remaining in the body at that time. This divided by the plasma water inulin concentration at the same time gives the first volume of distribution (VI_1). Similarly the weight of inulin injected minus the total weight excreted in both urine samples gives the weight remaining in the body at the time of the second urine collection, and this, divided by the second plasma water concentration of inulin gives the second 'volume of distribution' (VI_2).

The plasma water renal clearance of inulin (C'_{in}) is given by the formula

$$C'_{in} = \frac{b(\log_{10} P_1 - \log_{10} P_2)}{\log_{10} VI_1 - \log_{10} VI_2} - b$$

where P_1 and P_2 are the concentrations of inulin in mg per 100 ml of plasma water at the times of collection t_1 and t_2 (times in minutes measured from the midpoint of the injection). VI_1 and VI_2 are as described, the volumes of

distribution at these times (conveniently expressed in hundreds of millilitres),

$$b = \frac{V_{I_2} - V_{I_1}}{t_2 - t_1}$$

C'_{In} is readily converted to the conventional plasma clearance of inulin (C_{In}) in millilitres plasma per minute by multiplying by the factor

$$\frac{10\,000}{100 - g \text{ plasma protein}/100 \text{ ml}}$$

and for ordinary purposes the plasma protein concentration can be regarded as constant, so that

$$C_{In} = 106 \times C'_{In}$$

The following is a chart of the timing of the operations and an example of the calculation

Fig 1—Determination of the renal clearance of inulin

Plasma proteins = 7 g/100 ml
Total inulin injected at $t = 0$ was 7410 mg

	Minutes	Inulin excreted (mg)	Inulin retained in body (mg)	Plasma inulin conc/100 ml (mg)	Plasma-water inulin conc/100 (mg)	(V_{I_1})
t_1	30	1656	5754	48.3	51.9	111
t_2	100	3449	3961	29.6	31.8	125

$$b = \frac{125 - 111}{100 - 30} = 0.200$$

$$C'_{In} = \frac{0.200 (\log_{10} 51.9 - \log_{10} 31.8)}{\log_{10} 125 - \log_{10} 111} = 0.200 = 0.6248$$

$$\text{Plasma inulin clearance} = \frac{0.6248 \times 10\,000}{(100 - 7)} = 67.2 \text{ ml/min}$$

RENAL CLEARANCE OF DIODONE

The method is essentially similar to that for inulin clearance and so also is the calculation

Preparation and Injection of Diodone Solution

It is convenient to use, without dilution, the 35% (w/v) solution of diodone obtainable in sterile ampoules from Glaxo Laboratories Ltd (Greenford, Middlesex, England). The dose required is one which will give plasma diodone levels of not more than 5 mg per 100 ml (in terms of iodine) when the first blood sample is taken, and not less than 1 mg per 100 ml when the second sample is taken. In practice this means 7–8 ml of the solution for a person of 70 kg body weight and with normal renal function, but when severe depression of renal function is expected the dose should be reduced to 4 ml for 70 kg body weight. The injection, for which a 10 ml syringe is suitable, should take 1–2 minutes and the exact times should be recorded.

Toxic reactions to diodone in these amounts are uncommon, but include urticaria, tenesmus, flushing and vomiting.

Blood and Urine Collection

The procedure is similar to that after inulin injection, but because of the rapid elimination of diodone, the first blood and urine collections should be made 20 minutes, and the second 60 minutes, after the midpoint of the injection.

Chemical Analysis

Diodone is determined in plasma and urine samples by Alpert's method (1941) in which the diodone iodine is quantitatively oxidised by bromine to iodate, and this is titrated with sodium thiosulphate. The results for plasma are expressed as mg diodone iodine per 100 ml of plasma water, for urine the total diodone iodine in the sample is required.

Calculation

For the respective collection times t_1 and t_2 (measured in minutes from the midpoint of the injection) the "volumes of distribution," VD_1 and VD_2 , are calculated exactly as for inulin. These values are substituted in the formula

$$C'D = \frac{q (\log_{10} P_1 - \log_{10} P_2)}{\log_{10} VD_2 - \log_{10} VD_1} - q$$

in which

$C'D$ = the plasma water renal clearance of diodone
 P_1 and P_2 are the concentrations of diodone iodine in mg per 100 ml of plasma water at times t_1 and t_2
 VD_1 and VD_2 are as described, and are expressed in hundreds of millilitres

$$q = \frac{VD_2 - VD_1}{t_2 - t_1}$$

As in the case of inulin, the plasma-diodone clearance (C_D) in millilitres per minute is then given by the expression

$$C_D = 106 \times C'D$$

or more correctly,

$$C_D = \frac{10\,000 \times C'D}{100 - g \text{ plasma protein}/100 \text{ ml plasma}}$$

The following is an example of the timing of the procedure and an example of the calculation

Fig 2—Determination of the renal clearance of diodone

Plasma proteins = 7.0 g/100 ml
Total diodone iodine injected = 1646 mg

	Minutes	diodone iodine excreted (mg)	diodone iodine retained (mg)	Plasma diodone-iodine conc/100 ml (mg)	Plasma water diodone-iodine/100 (mg)	VD
t_1	28	385.7	660.3	3.64	3.91	168.9
t_2	55	560.9	485.1	2.25	2.49	200.5

$$q = \frac{200.5 - 168.9}{55 - 28} = 1.1704$$

$$C'D = \frac{1.1704 (\log_{10} 3.91 - \log_{10} 2.42)}{\log_{10} 200.5 - \log_{10} 168.9} = 1.1704 = 0.108$$

$$\text{Plasma diodone clearance} = \frac{2.108 \times 10\,000}{(100 - 7)} = 227 \text{ ml/min}$$

MAXIMAL TUBULAR EXCRETORY CAPACITY FOR DIODONE

For determination of the T_{MD} it is necessary to know the clearance of inulin and the rate of excretion of diodone when the plasma concentration of this latter substance is sufficiently high to ensure "saturation" of the renal tubules as defined by Smith (1943). The two determinations may be made separately, or, by giving an intra-venous injection of inulin immediately before the diodone, together. It is necessary to consider here only the procedure with respect to diodone.

Injection of Diodone

Experience shows that the required amount of diodone ranges from 350 to 200 mg per kg body weight according to the (expected) renal efficiency of the subject, the greater the efficiency the greater the dose. The solution used, 50% diodone (w/v) is obtainable, sterile in ampoules from Glaxo Laboratories, and an average sized subject is given 30 to 50 ml of this, at a rate not exceeding 5 ml per minute. When given in these quantities diodone occasionally produces uncomfortable side reactions which may include nausea, vomiting, tenesmus, colic, urticaria, faintness, fall

n blood pressure, itching, and pain over the site of the injection. The incidence and severity of such reactions are, however, minimised by the prescribed slow rate of injection.

Collection and Analysis of Samples

Measuring time as usual, from the midpoint of the injection, blood and urine are collected after approximately 30 and 100 minutes, the exact times being noted. For diodone (and inulin, if both determinations are made together) the method already mentioned is employed.

Calculation

The formula used is

$$T_{MD} = (C' + m) \frac{P_1 V_{D_1} x - P_2 V_{D_2} x}{V_{D_1} x - V_{D_2} x}$$

in which

t_1 and t_2 are the times of collection in minutes after injection.
 P_1 and P_2 are the plasma water concentrations of diodone iodine in mg per 100 ml.

V_{D_1} and V_{D_2} are the "volumes of distribution" of diodone at these times expressed in hundreds of millilitres and are calculated as described for inulin

$$m = \frac{V_{D_2} - V_{D_1}}{t_2 - t_1}$$

$C' = FW^2 C_{In}$, where

F = that fraction of the plasma-diodone which is free in the plasma water and is therefore filterable. (This depends on the total plasma-diodone concentration and the plasma albumin concentration see nomogram Smith and Smith 1935)

W = the water fraction of plasma (may be taken as 100 - plasma protein in g per 100 ml.)

C_{In} = the renal plasma-clearance of inulin expressed in hundreds of millilitres per minute

$$x = \frac{C' + m}{m}$$

With the units suggested, values for T_{MD} are obtained in milligrammes diodone-iodine excreted per minute—the conventional units

The following shows the procedure in diagrammatic form, together with an example of the calculation.

Fig 3—Determination of the maximal excretory capacity for diodone.

Amount of diodone-iodine injected 9860 mg

	Minutes after injection	Diodone-iodine excreted (mg)	Diodone-iodine retained (mg)	Plasma diodone-iodine conc./100 ml (mg)	Plasma water diodone-iodine/100 ml (mg)	V_D
t_1	28	1404	8556	51.6	53.5	154
t_2	98	4114	5846	29.8	32.0	183

$$m = \frac{183 - 154}{98 - 28} = 0.4143$$

$$C' = FW^2 C_{In} = 0.755 \times 0.8649 \times 0.672 = 0.4391$$

$$C' - m = 0.8534$$

$$C' + m = 0.8534$$

$$m = 0.4143$$

$$T_{MD} = (0.4391 + 0.8534) \times \frac{(29.8 \times 183) - (51.6 \times 154)}{154 - 183}$$

$$= 19.7 \text{ mg diodone-iodine per minute}$$

COMBINATION OF PROCEDURES

It is clear that the determination of the renal clearance of inulin may be combined with the determination either of the renal clearance of diodone or of the maximal excretory capacity for diodone. Estimation of both compounds may be made on the same blood or urine sample. It is most convenient to combine the procedure for inulin clearance with that of maximal tubular

excretory capacity for diodone (for which the former is in any case, required). The injection of diodone may follow immediately upon that of inulin, and both substances may be determined in the samples of blood and urine collected 30 and 120 minutes later. Under these circumstances, the determination of the renal clearance of diodone (C_D) may be performed on another occasion or in the hour immediately before the determination of inulin clearance and maximal tubular excretory capacity. In the latter event, the plasma diodone iodine level after 60 minutes is small enough to be ignored when the further large dose of diodone for T_{MD} determination is given.

DISCUSSION

The procedures described permit estimation of the renal clearance of inulin and diodone, and the maximal tubular excretory capacity for diodone, with very little inconvenience to the patient. Their general application would provide more informative data about discrete renal function than the orthodox renal function tests which estimate merely the resultant of several renal activities.

Comparing the results obtained employing the formulae described here, and those obtained employing the single injection technique and the collection of urine over short clearance periods, with direct application of the formulae

$$\text{Clearance} = \frac{UV}{P} \text{ and } T_{MD} = UV - FWC_{In} P$$

we have found that they correspond well (Robson et al 1949a and b). Correspondence between the results obtained by the single injection method and the more laborious continuous infusion technique has been shown to be good only for measurements of inulin clearance and maximal tubular excretory power for diodone (Ferguson et al 1950).

A systematic error is introduced into the determination of the renal clearance of diodone by any method which involves the single injection technique when venous blood is used for sampling, because of the large arterio-venous difference in diodone iodine concentration which arises from the magnitude of the renal plasma flow relative to the cardiac output (Olbrich et al 1950). It could probably be abolished by the rather drastic procedure of adopting arterial puncture for diodone iodine, when employing the single injection method for diodone clearance. This error does not, however, reduce the significance of the fractions which may be derived from the estimation of the renal functions by employing the single injection method, though it alters their magnitude as compared with those obtained by infusion techniques. The great ease with which the single injection method, combined with the formulae given here, permits the estimation of the discrete renal functions outweighs the modification of the absolute values for derived fractions which becomes necessary.

The authors gratefully acknowledge a grant to one of them (C P S) from the Nuffield Foundation, which made possible the participation of M H F in the work. They thank, in addition the Moray Research Fund of Edinburgh University for a grant which defrayed part of the cost of materials. They also thank Mr David B Horn for assistance in the chemical analyses and computations.

THAT decamethonium may be used clinically to produce muscular relaxation in anaesthesia and in convulsion therapy, as suggested by us (Paton and Zaimis 1948a), is now well established (Organe 1949, Davies and Lewis 1949, Hobson and Prescott 1949, Hewer et al 1949, Davies 1950). But it is clear from some reports that the fundamental differences in mechanism of action between decamethonium and drugs resembling *d* tubocurarine are not sufficiently appreciated, and that this lack of understanding may interfere with assessment of the value of such drugs.

MODE OF ACTION OF DECAMETHONIUM AND *d* TUBOCURARINE

The fundamental action of decamethonium on skeletal muscle is a specific depolarisation of the muscle membrane at the motor end plate (where the motor nerve fibre ends on the muscle membrane) (Burns and Paton 1950). The first effect of this depolarisation, particularly if the decamethonium is injected rapidly into a muscle by an arterial route, is to excite a brief contraction. But the depolarisation then persists and spreads to adjacent regions of the muscle. Two further effects follow: (1) because the end plate is already partly depolarised, a nerve impulse can no longer evoke so large an "end-plate potential" (the electrical response by which the muscle fibre is excited), and (2) the surrounding depolarised area becomes electrically inexcitable, with the result that there is a zone of inexcitable muscle membrane 2-3 mm in width between the point at which the end plate potential is set up and the nearest normally excitable part of the muscle fibre. The net result of the reduction of the end plate potential, and of the inexcitability of the end plate zone, is neuromuscular block.

This action of decamethonium is analogous to that exerted by acetylcholine. Normally, in mammalian muscle, acetylcholine released at the nerve terminals depolarises the end plate for only a few thousandths of a second, so giving rise to the normal end plate potential, and its liberation and removal are so rapid that only excitation is seen. But if acetylcholine is caused to persist either by giving anti-cholinesterases or by injecting large doses into a muscle, so that the depolarisation which it causes is prolonged, neuromuscular block follows, with the same characteristics as block due to decamethonium (Zaimis 1949).

In short, it may be said that, so far as skeletal muscle is concerned, decamethonium can be regarded as an acetylcholine that cannot be hydrolysed, and its actions are the same as those of persisting acetylcholine. Thus the contractions sometimes evoked by decamethonium are precisely analogous to those of any voluntary movement but are less co-ordinated. Decamethonium does not share the other (muscarine like and ganglion-stimulating) actions of acetylcholine, but its properties are simply those exerted by acetylcholine at the myoneural synapse, displayed in singularly pure form.

In contrast with decamethonium, *d* tubocurarine cannot depolarise the muscle, and its actions depend on its ability to prevent other agents, especially acetylcholine, from doing this. In this way it makes the

end plate potential, evoked by the discharge of acetylcholine at the nerve terminals, too small to excite the muscle fibre, although the muscle fibre is still normally excitable by electrical stimulation.

The actions of decamethonium can therefore be regarded as due to an abnormally persistent end plate depolarisation, and those of *d* tubocurarine to the blocking of the normal depolarising action of acetylcholine, thus the mechanisms of action are diametrically opposed. This is elegantly illustrated by the fact that *d* tubocurarine can antagonise the effects of decamethonium. The terms "curarising" or "curariform" are now seen to be words that must be used with care, and are best restricted to those drugs which, like *d* tubocurarine, act simply by raising the threshold of the motor end plate to acetylcholine.

CONSEQUENCES OF DIFFERENCE IN ACTION

The divergence in the ways by which decamethonium and *d* tubocurarine act inevitably leads to many detailed differences in their behaviour. For instance, it follows at once that it is not to be expected that anti-cholinesterases should antagonise decamethonium, since prolongation of the action of acetylcholine in a muscle paralysed with decamethonium can do little more than intensify the block slightly. So too there are many other differences in the mode of onset and passing of the paralysis, in the influence of anaesthetics, in the response to repetitive nerve stimulation, to mention only a few.

The use of neuromuscular blocking agents has evolved over a period of years, around preparations containing *d* tubocurarine.

Decamethonium is the first, and so far the only, "depolarising" blocking agent to be used clinically. A technique developed with *d* tubocurarine will therefore need adaptation if it is to be used to full advantage with decamethonium. Seriously misleading results may be obtained if the differences between the drugs are not borne in mind, and the following examples have been chosen to exemplify this.

Muscle Specificity

It has long been known that muscles vary in their sensitivity to *d* tubocurarine, the muscles of the eyes, pharynx, and larynx being particularly susceptible. Hence it is not surprising that decamethonium should also display differences in its effect on different muscles. But the significant point is that these differences are not the same as with *d* tubocurarine. Figs 1 and 2 illustrate this point on the tibialis anterior and the soleus in the cat, with *d* tubocurarine the soleus is the more easily paralysed (fig. 2), whereas with decamethonium the tibialis is paralysed first (fig. 1). Similarly, in the cat,

Fig. 1—Tracings of maximal twitch tension from records of the contraction of tibialis and of soleus excited by single maximal nerve shocks every 10 sec. in a cat weighing 3.3 kg. in chloralose anaesthesia after injections of decamethonium and of decamethonium with adrenaline.

the respiratory muscles are paralysed before the tibialis with *d*-tubocurarine and after the tibialis with decamethonium (Paton and Zaimis 1948b).

This varying sensitivity to the two drugs may be seen in another aspect when different species are compared. We then find that in the rat, on which *d*-tubocurarine is more than usually potent, decamethonium is particularly ineffective, whereas in the cat, on which

Fig 2—Tracings as fig 1 in a cat weighing 3.5 kg., in chloralose anaesthesia, after injections of *d*-tubocurarine and of *d*-tubocurarine with adrenaline.

d-tubocurarine is less effective, decamethonium reaches its highest potency.

Yet another difference is that ether anaesthesia slightly potentiates *d*-tubocurarine, but slightly antagonises decamethonium (Paton and Zaimis 1949).

In short, one may say that the circumstances in which *d*-tubocurarine is

particularly effective are likely to be those in which decamethonium is ineffective, and vice versa. This inverse relationship between the two drugs springs naturally from the difference in their modes of action, and provided an important clue to that difference. But it also has an important bearing on clinical comparisons between the drugs.

Effects of Adrenaline

(1) In an anaesthetised animal the stimulant effects of decamethonium on a muscle are usually restricted to a few transient fasciculations, with more or less potentiation of the nerve excited muscle twitch. If a dose of adrenaline is given beforehand, however, this excitatory phase may be distinctly increased and the fasciculations become quite vigorous. This effect may be observed whether the adrenaline is given arterially or intravenously, and with noradrenaline.

(2) Adrenaline also influences the depth of paralysis of the muscle by decamethonium. Fig 1 shows how, with the tibialis muscle of the cat, the injection of adrenaline intravenously lessens the maximum paralysis by decamethonium from 95% to 78%. On the other hand, with *d*-tubocurarine (fig 2) an intravenous dose of adrenaline just before the injection increases the blocking effect on tibialis from 60% to 75% block and prolongs it.

(3) But these changes of potency of decamethonium and *d*-tubocurarine do not affect different muscles equally or in the same direction. Fig 1 shows, for instance, that with the soleus muscle adrenaline has quite opposite effects to those on tibialis, here it actually augments the action of decamethonium. With *d*-tubocurarine, however, adrenaline hardly modifies the action on soleus and increases it on tibialis (fig 2).

The presence of circulating adrenaline therefore, has three effects: (1) it increases the stimulant action of decamethonium; (2) it changes the potency of *d*-tubocurarine and of decamethonium on a given muscle; and (3) it changes the pattern of muscle susceptibility

to these two drugs in opposite ways, increasing the proportionate effect of decamethonium on the "red" muscle, soleus, and decreasing that of *d*-tubocurarine on soleus. There can be little doubt that tests of these compounds in conscious people will be seriously influenced by the secretion of adrenaline that accompanies trials of this nature.

Idiosyncrasy

Among the precautions taken in the administration of *d*-tubocurarine is that of giving an initial small dose, so as to detect those occasional persons who are particularly susceptible to it, and who (it has been suggested) may be regarded as latent or subclinical myasthenics. The same technique has been used with decamethonium (Gray 1950). But when we consider the modes of action of the two drugs, and the evidence already cited that conditions favouring the action of *d*-tubocurarine usually oppose that of decamethonium, it seems reasonable to expect that those patients who are susceptible to decamethonium. Some slight support for this suggestion that there is no idiosyncrasy of this kind to decamethonium comes from the experience of Davies (1950) in which, out of 973 administrations of decamethonium, every patient required 3–5 mg, and none appeared to be particularly sensitive. It would be of great interest to know what the sensitivity of a myasthenic is to decamethonium, since it would not only determine whether idiosyncrasy of this kind occurred to decamethonium but would also throw light on the pathogenesis of myasthenia.

It therefore seems probable that precautionary small initial doses are unnecessary with decamethonium. They may also be somewhat confusing to an inexperienced anaesthetist. The effects of a small dose of decamethonium in a conscious patient with (no doubt) a liberal supply of circulating adrenaline due to the approaching operation are likely to be solely those of muscle stimulation. These contractions are, as we have said above, perfectly harmless, being analogous to an incoordinated voluntary contraction; they pass off within a minute or two, or with the administration of more decamethonium.

CLINICAL ASSESSMENT

The considerations and evidence which we have advanced have one particularly important consequence: that, for practical purposes a comparison of the clinical usefulness of such drugs as *d*-tubocurarine and decamethonium can only be made under the conditions of actual use. If it is desired to know for instance, whether one or other of such drugs has (say) less effect on the respiration than on the abdominal muscles in an anaesthetised patient, then the comparison must be made on the muscles concerned and in anaesthetised patients. It is instructive to compare two attempts at such a comparison, with this requirement in mind.

The first is that of Davies and Lewis (1949) who wished to compare the effects on the respiration of decamethonium and *d*-tubocurarine when given to abate the convulsions of shock therapy. The comparison was made directly, in the course of normal treatment. By a simple but careful system of scoring the intensity of the convulsions, doses of each drug which were equally active were obtained. Using these doses, these workers determined the maximum inspiratory capacity of the patients just before the convulsion. They found that, for the third and fourth minutes after the injection this was 1160 c.c.m. and 1110 c.c.m. respectively with decamethonium, and 835 c.c.m. and 700 c.c.m. with *d*-tubocurarine (average of six patients). This was not an elaborate study but its findings were clear and directly applicable to practice; they have been borne out by later experience. It remains the only satisfactory clinical comparison yet made between two such drugs.

ACTIONS AND CLINICAL ASSESSMENT OF DRUGS WHICH PRODUCE NEUROMUSCULAR BLOCK

That decamethonium may be used clinically to produce muscular relaxation in anaesthesia and in convulsion therapy, as suggested by us (Paton and Zaimis 1948a), is now well established (Organe 1949, Davies and Lewis 1949, Hobson and Prescott 1949, Hewer et al 1949, Davies 1950). But it is clear from some reports that the fundamental differences in mechanism of action between decamethonium and drugs resembling *d* tubocurarine are not sufficiently appreciated, and that this lack of understanding may interfere with assessment of the value of such drugs.

MODE OF ACTION OF DECAMETHONIUM AND *d* TUBOCURARINE

The fundamental action of decamethonium on skeletal muscle is a specific depolarisation of the muscle membrane at the motor end plate (where the motor nerve fibre ends on the muscle membrane) (Burns and Paton 1950). The first effect of this depolarisation, particularly if the decamethonium is injected rapidly into a muscle by an arterial route, is to excite a brief contraction. But the depolarisation then persists and spreads to adjacent regions of the muscle. Two further effects follow: (1) because the end plate is already partly depolarised, a nerve impulse can no longer evoke so large an "end plate potential" (the electrical response by which the muscle fibre is excited), and (2) the surrounding depolarised area becomes electrically inexcitable, with the result that there is a zone of inexcitable muscle membrane 2-3 mm in width between the point at which the end plate potential is set up and the nearest normally excitable part of the muscle fibre. The net result of the reduction of the end plate potential, and of the inexcitability of the end plate zone, is neuromuscular block.

This action of decamethonium is analogous to that exerted by acetylcholine. Normally, in mammalian muscle, acetylcholine released at the nerve terminals depolarises the end plate for only a few thousandths of a second, so giving rise to the normal end plate potential, and its liberation and removal are so rapid that only excitation is seen. But if acetylcholine is caused to persist either by giving anti-cholinesterases or by injecting large doses into a muscle, so that the depolarisation which it causes is prolonged, neuromuscular block follows, with the same characteristics as block due to decamethonium (Zaimis 1949).

In short, it may be said that, so far as skeletal muscle is concerned, decamethonium can be regarded as an acetylcholine that cannot be hydrolysed, and its actions are the same as those of persisting acetylcholine. Thus the contractions sometimes evoked by decamethonium are precisely analogous to those of any voluntary movement but are less co-ordinated. Decamethonium does not share the other (muscarine like and ganglion-stimulating) actions of acetylcholine, but its properties are simply those exerted by acetylcholine at the myoneural synapse, displayed in singularly pure form.

In contrast with decamethonium, *d* tubocurarine cannot depolarise the muscle, and its actions depend on its ability to prevent other agents, especially acetylcholine, from doing this. In this way it makes the

end plate potential, evoked by the discharge of acetylcholine at the nerve terminals, too small to excite the muscle fibre, although the muscle fibre is still normally excitable by electrical stimulation.

The actions of decamethonium can therefore be regarded as due to an abnormally persistent end plate depolarisation, and those of *d* tubocurarine to the blocking of the normal depolarising action of acetylcholine, thus the mechanisms of action are diametrically opposed. This is elegantly illustrated by the fact that *d* tubocurarine can antagonise the effects of decamethonium. The terms "curarising" or "curariform" are now seen to be words that must be used with care, and are best restricted to those drugs which, like *d* tubocurarine, act simply by raising the threshold of the motor end plate to acetylcholine.

CONSEQUENCES OF DIFFERENCE IN ACTION

The divergence in the ways by which decamethonium and *d* tubocurarine act inevitably leads to many detailed differences in their behaviour. For instance, it follows at once that it is not to be expected that anti-cholinesterases should antagonise decamethonium, since prolongation of the action of acetylcholine in a muscle paralysed with decamethonium can do little more than intensify the block slightly. So too there are many other differences in the mode of onset and passing of the paralysis, in the influence of anaesthetics, in the response to repetitive nerve stimulation, to mention only a few.

The use of neuromuscular blocking agents has evolved over a period of years, around preparations containing *d* tubocurarine. Decamethonium is the first, and so far the only, "depolarising" blocking agent to be used clinically. A technique developed with *d* tubocurarine will therefore need adaptation if it is to be used to full advantage with decamethonium. Seriously leading results may be obtained if the differences between the drugs are not borne in mind, and the following examples have been chosen to exemplify this.

Muscle Specificity

It has long been known that muscles vary in their sensitivity to *d* tubocurarine, the muscles of the eye, pharynx, and larynx being particularly susceptible. Hence it is not surprising that decamethonium should also display differences in its effect on different muscles. But the significant point is that these differences are not the same as with *d* tubocurarine. Figs 1 and 2 illustrate this point on the tibialis anterior and the soleus in the cat, with *d* tubocurarine the soleus is the more easily paralysed (fig 2), whereas with decamethonium the tibialis is paralysed first (fig 1). Similarly, in the cat,

Fig 1—Tracings of records of the contraction of maximal twitch tension from records of the contraction of tibialis and of soleus excited by single maximal nerve shocks every 10 sec. in a cat weighing 3.3 kg. in chloralose anaesthesia after injections of decamethonium and of decamethonium with adrenaline.

The dosage of TBI-69S is small by comparison with that of P.A.S. 200 mg of TBI 69S per day (or exceptionally 300 mg) is generally regarded as the maximum. The method described here has therefore been designed to record even low blood levels of the drug.

METHOD

Solutions—The following are needed

- 1 Stock solution of TBI-69S. A commercial sample of this substance is recrystallised twice from *n*-butyl alcohol, and the solution is prepared by dissolving 50 mg of TBI-69S in 100 ml of absolute ethyl alcohol. Since thiosemicarbazones of this type are photolabile the solution should be stored in a dark cupboard.
- 2 Standard solution of TBI-69S. Prepared by diluting 20 ml of the stock solution to 100 ml with water. Store in the dark.
- 3 20% trichloroacetic acid.
- 4 0.2% sulphuric acid.
- 5 0.02% sodium nitrite. Prepared freshly by dilution of a 0.5% solution which is stored in the ice-chest.
- 6 0.5% dimethyl- α -naphthylamine. Prepared by dissolving 0.5 ml of the amine in 100 ml of absolute ethyl alcohol.

Technique—1 ml. of serum, plasma, or whole blood, is mixed with 3.2 ml of water and 0.8 ml of 20% trichloroacetic acid is added slowly with agitation. The mixture, after standing for a few minutes is centrifuged, or filtered through a small filter paper. 2 ml of filtrate is placed in a 10 ml graduated centrifuge tube or in a test-tube which has been calibrated at 4 ml by means of a diamond pencil. 0.5 ml of 0.2% sulphuric acid is added and the tube placed in a boiling water bath for 45 min. The tube is then cooled under the tap and 0.5 ml of 0.02% sodium nitrite solution is added. After standing for 3 min. 1 ml of 0.5% dimethyl- α -naphthylamine is added, and the final volume is adjusted to 4 ml with distilled water. Removal of excess nitrous acid by urea or ammonium sulphamate is unnecessary under these conditions.

The colour develops almost at once and is stable for some time if not exposed to direct sunlight. The coloured compound absorbs light maximally at 530 m μ , and a green filter should be used in the colorimeter, a Chance 0.61 filter is suitable. A standard is carried through simultaneously by substituting for blood 1 ml. of standard TBI 69S solution. A reagent blank may also be prepared by replacing the blood by 1 ml. of water but the values so obtained have been negligible small.

With a Hilger 'Biochem' absorptiometer, the method has proved satisfactory down to levels of 0.4 mg per 100 ml blood. Development of the final colour depends on the concentration of acid present, and hydrolysis of the *p*-acetamidobenzaldehyde thiosemicarbazone must be carried out under less strongly acid conditions than are used in the estimation of acetylated sulphonamides (Bratton and Marshall 1939). The colours obtained with TBI 69S are considerably stronger than those for the corresponding concentration of P.A.S.

RESULTS

The proportions recovered when TBI 69S was added to 1 ml plasma were as follows

Added (μ g)	Recovered	Proportion of amount added (%)
6.0	5.4	90
10.0	8.9	89
12.0	10.2	85
20.0	17.6	88
30.0	26.4	88

* Mean recovery 88.5%

Since the substance is very sparingly soluble in water it must presumably, like P.A.S., be carried in the bloodstream in association with protein. The efficacy of any method for its estimation will therefore depend on the way in which the protein is precipitated.

Medical Societies

BRITISH ORTHOPÆDIC ASSOCIATION

Annual Meeting

THE annual meeting of the association was held in London on Oct. 26, 27, and 28, under the presidency of Mr S. L. HIGGS.

Place of Femoral Lengthening in Leg Equalisation—Mr DENYS WARDWRIGHT (Newcastle) discussed the problem of leg equalisation in such conditions as poliomyelitis, congenital short femur, and premature epiphyseal fusion. Femoral lengthening had been a controversial subject but he believed that it had a definite place in treatment. Among 25 patients who had been operated on the average gain in length was 2 in. Complications included delayed union 1, stiffness of the knee 2, and temporary nerve paralysis 2. There were no vascular complications. Mr F. G. ALLAN (Birmingham) agreed that knee stiffness presented a real problem.

Immobilisation Osteoporosis—Dr HARWOOD STEVENSON (Stanmore) had studied the radiographs of 100 patients submitted to long immobilisation for various diseases, and had found that the process of osteoporosis followed a typical pattern irrespective of the nature of the primary disease. Immobilisation osteoporosis developed rapidly and might be obvious within six weeks. But if mobility was maintained disease might be present in a limb for many months without leading to marked osteoporosis. These observations suggested that osteoporosis was a consequence of immobilisation as such rather than of disease.

Osteoporosis and Epiphyseal Changes in Diseased and Immobilised Limbs—Dr H. A. Sissons had studied the gross and microscopic structure of bone obtained from osteoporotic limbs and from the site of prematurely fused epiphyses. Examination of trabecular structure was aided by radiographs of thin bone sections. In areas of bone atrophy osteoclasts and osteoblastic new-bone formation proceeded concurrently. Hyperemia was not evident. In sections from areas of premature epiphyseal fusion there was disruption of the epiphysis into the diaphysis and bony bridging of the epiphyseal line. The evidence suggested that the process of atrophy during immobilisation was one of osteoporosis in the strict sense of the word, and was not simply a halteresis. The process was not due to hyperemia alone. Mr H. JACKSON BURROWS said that in normal bone there was a continual and balanced process of absorption and laying down of bone. In disuse atrophy there was diminished replacement of bone, and increased absorption. The stimulus responsible for this was unknown. Vascularity had little to do with it, and it was noteworthy that a general stimulus might affect only local areas of bone.

Curve Patterns in Idiopathic Structural Scoliosis—Mr J. I. P. JAMES recalled that recent work in America had shown that the pattern of the curve in idiopathic scoliosis was the key to the prognosis. He reported a study of the typical features and prognosis in two curve patterns—infantile idiopathic scoliosis and primary lumbar idiopathic scoliosis. In infantile idiopathic scoliosis the prognosis had been assessed from analysis of 33 cases. Exceptionally a curve that was initially slight might disappear, a few might remain stationary, but most curves progressed and led to severe deformity. Treatment was very unsatisfactory. Primary lumbar idiopathic scoliosis had a benign course, correction was not required. However pain, developing in middle life from osteoarthritis, was much more common in this than in other patterns of scoliosis. If not relieved by a suitable corset, fusion (without correction) might be required. Mr H. OSMOND CLARKE remarked that study of the curve patterns simplified prognosis but not treatment. Infantile scoliosis was a ferocious problem to which no solution was known. All patients with scoliosis should be segregated in specially equipped clinics.

Experimental Causation of Congenital Defects—Dr P. K. DURASWAMI (Liverpool) illustrated experiments in which insulin had been injected into the yolk of fertilised hens' eggs. A high proportion of the chickens developed congenital deformities which often affected

In contrast one may cite the relatively complicated experiments of Unna et al (1950). These workers wished to assess the usefulness in surgical anaesthesia of three blocking agents, paying particular attention to the respiratory effects. They were careful to emphasise the danger of arguing from experiments on one species to another, but they underestimated the equally great danger of arguing from one muscle to another. So far from studying the abdominal muscles, they chose the muscles of the hand for analysis. They obtained, as doses giving 95% paralysis of the grip strength, the following average doses for a man weighing 70 kg: *d* tubocurarine chloride 9.4 mg, decamethonium iodide 2.8 mg. If these doses are compared with the amounts that have been found to give equivalent maximum relaxations in anaesthesia (*d* tubocurarine chloride 15 mg, decamethonium iodide 3 mg), it is seen at once that the hand must be relatively more sensitive than the abdominal muscles to *d* tubocurarine. Roughly speaking, then, the dose of *d* tubocurarine required to paralyse the hand was only 65% of that needed for abdominal relaxation, whereas for decamethonium the dose was 95% of the effective dose for anaesthesia. The comparison of the effects on the respiration was therefore between a full anaesthetic dose of decamethonium and a two-thirds anaesthetic dose of *d* tubocurarine. Such a comparison is obviously irrelevant to the conditions of surgical anaesthesia, although of some interest for manual physiology.

Further, instead of using anaesthetised persons, Unna et al used conscious volunteers, in whom adrenaline must have been secreted in appreciable amounts (these workers themselves state that "an increase in pulse rate and blood pressure in the subjects was seen frequently during the first few minutes after the injection of any of the drugs"). We have shown how circulating adrenaline profoundly alters the comparison between decamethonium and *d* tubocurarine, in a way which seems likely to increase the respiration-sparing effects of *d* tubocurarine and to decrease those of decamethonium. The comparison by Unna et al was made under conditions different from those of anaesthesia and probably those least favourable to decamethonium. To the presence of circulating adrenaline may be attributed also the muscular twitches and muscle cramps recorded with decamethonium by these observers. We ourselves observed in the first trials of decamethonium (Organe et al 1949) that the incidence of the cramps was in proportion to the rise in blood pressure during the experiment.

It is clear, therefore, that the experiments by Unna et al, through an unfortunate chance, were made in such a way that the respiratory depressant effects of decamethonium were likely to be exaggerated, its muscle specificity reduced, and its muscle stimulating action increased. It is not surprising that these workers were unable to confirm the finding of Davies and Lewis (1949) that decamethonium has a less depressant action than has *d* tubocurarine on respiration.

DISCUSSION

We have emphasised particularly the difficulties in making comparisons between *d* tubocurarine and decamethonium. But the difficulties of assessments of this sort are not restricted to these two drugs; they will appear when any two or more drugs that produce neuromuscular block are studied, and will certainly also have to be faced in the clinical evaluation of the dimethyl ether of *d* tubocurarine, and of 'Flaxedil,' not to mention that of the blocking agents still to be discovered. Although it is considerably harder to make quantitative comparisons during clinical practice than in the laboratory, there seems no escape from the conclusion that either this task must be undertaken or we must remain in doubt about the relative usefulness of these drugs in practice. Such trials, however, have

an interest greater than that of simple clinical evaluation of a new medicament, for they reveal differences between the drugs that may be, in time, capable of exploitation in other directions, in particular, it seems possible that the varying muscle specificity may prove useful. Further, there is slowly accumulating a substantial body of information relating the physiology of the human neuromuscular junction—about which we have little detailed knowledge—to the well established and extensive information at our disposal in animals.

SUMMARY

Decamethonium and *d* tubocurarine cause neuromuscular block by fundamentally different mechanisms. Block by decamethonium is due to a persistent end-plate depolarisation, analogous to an exaggeration of the normal excitant action of acetylcholine; block by curare is due to an antagonism to the normal action of acetylcholine.

These differences in mode of action reveal themselves in many ways, particularly in differing muscle susceptibility. Further, circulating adrenaline modifies the pattern of muscle susceptibility both of *d* tubocurarine and of decamethonium.

The relevance of these findings to clinical assessment of such drugs is discussed. Such assessment can be valid only if made under the actual conditions in which the drug is to be used.

COLORIMETRIC ESTIMATION OF *p*-ACETAMIDOBENZALDEHYDE THIOSEMICARBAZONE IN BLOOD

D G MOSS

M Sc Manc

BIOCHEMIST, WITHINGTON HOSPITAL MANCHESTER

THE German drug, *p*-acetamidobenzaldehyde thiosemicarbazone ('TBI 698' or 'Conteben') has given promising results in the treatment of some forms of tuberculosis (Hinshaw and McDermott 1950, *Lancet* 1950, Mortens and Bunge 1950). This substance, which is now manufactured in Great Britain, is potentially highly toxic, and since treatment may be continued for 6-12 months careful supervision is essential.

Ultraviolet absorption spectroscopy was used by Spinks (1949) to measure in mice the blood level of substituted benzaldehyde thiosemicarbazones prepared by Hoggarth and his co-workers (1949), but comparable figures for TBI 698 in man do not seem to have been published. In contrast to many of the thiosemicarbazones whose chemotherapeutic activities were examined by Hoggarth et al, the colorimetric estimation of TBI 698 is comparatively simple, since it can be hydrolysed to the corresponding derivative of *p*-aminobenzaldehyde, which is then diazotised and coupled with a suitable aromatic amine. This method is not specific for TBI 698, for *p*-aminosalicylic acid (PAS) and the sulphonamides will also give colours. However, the concurrent administration of sulphathiazole, which was practised in the early German work, has been abandoned because of toxic effects.

strated new types of elbow-crutch and walking-stick which have been developed at the Birmingham Accident Hospital

Pigmented Villonodular Synovitis—Mr G R FISK had studied 6 cases of pigmented villonodular synovitis—a condition affecting a single joint, usually the knee. It occurred in two forms, generalised and localised. The generalised form was often preceded by injury and was characterised by persistent swelling and effusion of the joint, which might resemble a tuberculous infection. Pathologically, the synovium was greatly thickened and chocolate-brown in colour. In early cases the thickened villi gave a matted seaweed appearance. Later there was generalised thickening with formation of nodules. Histologically, the main features were proliferation of surface cells, marked vascularity, proliferation of connective tissue, intracellular and extracellular deposits of haemosiderin and lipid, and frequent reticulo-endothelial cells. Treatment was by synovectomy, and provided removal was complete the prognosis was good. The localised form, sometimes termed benign synovoma, occurred as a circumscribed nodule, often near the joint-line. If pedunculated it might cause recurrent locking of the joint suggestive of a cartilage tear. Treatment was by excision of the nodule.

Actinomycosis of Bone—Mr V ZACHARY COPE reviewed the characteristic features of actinomycosis with particular reference to bone infection. He emphasised that the actinomycetes found so commonly in the soil seldom caused human or animal disease and that the causative organism was almost invariably derived from the human digestive tract. The bone most commonly affected was the mandible. In the spine, any area of which might be affected, actinomycosis usually attacked the superficial parts of the bone, but unlike tuberculosis it commonly involved the transverse or costal processes as well as the vertebral body. Collapse of the body was exceptional and the intervertebral disc was resistant to infection, so deformity was slight. Early diagnosis was important, for if left untreated the disease proved fatal within two or three years, whereas if it was treated efficiently by very large doses of penicillin or streptomycin, supplemented by blood-transfusion and general therapy, there was a good prospect of permanent cure.

Internal Fixation of the McMurray Osteotomy with a Trifin Nail—Mr ROBERT ROAF (Liverpool) had devised a simple method of internal fixation of the femoral fragments after displacement osteotomy of the McMurray type. The method consisted in driving a long trifin nail from the tip of the greater trochanter downwards and medially into the upper part of the shaft fragment.

Controlled Pseudarthrosis for Fracture of the Neck of the Femur—Mr E MERVYN EVANS (Swansea) described a method of treating ununited fractures of the neck of the femur which was applicable to very frail patients. He recalled that when osteotomy failed to stimulate union of the fracture a relatively painless pseudarthrosis might develop at the site of the fracture and might give reasonable function. He had attempted to produce such a pseudarthrosis deliberately by encouraging movement after osteotomy while ensuring fixation and union at the site of osteotomy by internal fixation.

Generalised Bone Decalcification—Dr C E DENT gave an account of some of the rarer forms of generalised bone decalcification, and particularly the uncommon cases of rickets or osteomalacia which were resistant to vitamin D. He believed that in all these cases the primary cause was impaired reabsorption by the renal tubules. In one type there was simply impaired reabsorption of phosphates (low renal threshold for phosphates) with consequently a low level of phosphates in the blood and a high level in the urine. In a second type this abnormality was accompanied by a lowered renal threshold for glucose with consequent glycosuria and thus merged into a third type in which there was also impaired reabsorption of amino acids, which appeared in the urine (Fanconi type, cystine rickets). These conditions were inherited. A further type, distinct from the above and not inherited, was that in which the renal tubules were unable to make ammonia and excrete an acid urine. Acidosis occurred, and calcium might be deposited in the kidneys. The skeletal changes were the same whatever the nature of the tubular insufficiency.

Reviews of Books

Blood Groups in Man

R R RACE, PH.D. Camb., M.R.C.S., director, Medical Research Council Blood Group Research Unit, London,
RUTH SANGER, PH.D. Lond., a member of the unit
Foreword by Prof R A FISHER F.R.S. Oxford Blackwell Scientific Publications 1950 Pp 290 30s

To serologists geneticists and medicolegal specialists the blood-groups are a valuable tool, to clinicians and to many pathologists they are a necessary evil. Both categories, however, need to be informed of the great advances of the past ten years, and they will agree in welcoming this up-to-date book. On the clinical and anthropological aspects of the subject the publishers promise separate works, but outside these confines it is remarkably comprehensive. It includes even the Duffy blood groups, only announced this year, and an account, incorporating work done only a few weeks before the book was published, of a possible deletion in a human Rh chromosome.

The general arrangement is historical: the blood-group systems are described in the order in which they were discovered and there is a clear account of the discovery of each. The authors were themselves personally concerned in the discovery of many blood-group antigens but they discuss their own work as objectively as the rest, indeed if they have a fault it lies in their occasional failure to point out that other workers sometimes base conclusions on criteria less rigid than those they use themselves. More than two-fifths of the text is devoted to the Rh factor and methods of Rh testing. Direct clinical applications of blood-group investigation are only briefly touched on, but the scientific background of these applications is fully demonstrated. Evidence for the mode of inheritance of each blood group antigen is critically assessed, and there is a valuable chapter on medicolegal applications.

Ophthalmic Operations

SEYMOUR PHILPS F.R.C.S., surgeon-in-charge of the eye department St Bartholomew's Hospital, surgeon to the Moorfields Westminster, and Central Hospitals, London
Baillière Tindall & Cox 1950 Pp 390 50s

NOTHING but the title of the old "Grimsdale and Brewerton" remains here. Mr Philps's book is beautifully illustrated by his own drawings and photographs. The text as a whole may not please everybody for the style is often colloquial, and there is some unnecessary repetition of the precautions to be observed in intra-ocular surgery. The descriptions of many operations are hardly detailed enough for postgraduates, and not every ophthalmic surgeon would agree with all the statements—for instance, that the only contra-indication to intracapsular extraction is that the patient is less than 50 years of age—or with all the techniques recommended. The account of the pathology and morbid histology of glaucoma and hydrophthalmia is in places confusing, and perhaps too little space is given to reconstructions (plastic) surgery, leading to the omission of points that deserve attention. On the other hand, Mr Philps's descriptions of the selection and care of instruments, and the emphasis he gives to the details of strict aseptic care in the preparation and conduct of eye operations, are admirable, and the high quality of the illustrations make this book a valuable guide for ophthalmic surgeons.

The Child and the Magistrate

JOHN A F WATSON London Cape 1950 Pp 367 12s 6d

The chairman of the South East London Juvenile Court has produced an outstandingly intelligent and well-informed study of his work in dealing with delinquent children. There have been few studies which present in such readable and critical terms the exact problem which such a court, balancing the requirements of law and fair trial and the welfare of the child, has to face. Mr Watson is fully aware of the value as well as the limitations of the psychiatrist's report, and moreover he emphasises the importance of the bench's

the skeleton. The type of deformity depended on the timing of the injection: thus injection during the first two days of incubation caused defects of the vertebral column, on the third day, the feet, on the fourth to fifth day, the limbs and beak. Abnormalities that had been produced included spina bifida, scoliosis, club-foot, dislocations of the knees, pseudarthrosis, osteogenesis imperfecta, achondroplasia, and chondro-osteodystrophy. It seemed that the injected substance affected organs at the time of their maximal development: there was a critical period for each organ. In a few instances deformities had recurred in the next generation. Once the tendency to deformity had been induced deformity occurred even if subsequent development took place in an environment free from insulin. But the development of deformity could be prevented by injection of nicotinamide and riboflavin.

Sprung Back—Mr P H NEWMAN described recent investigations into the pathology of a common clinical type of low back pain characterised by onset in young adults, often preceded by injury, increase of pain on flexion and relief with extension, and local midline tenderness and a palpable depression between two adjacent lower lumbar spinous processes without other objective findings. He believed that the underlying cause was disruption of the posterior intervertebral structures by a flexion injury. Healing by fibrosis occurred, but full stability was not regained. Once the back had been sprung painful redisplacement might take place whenever the protective extensor muscles were off their guard.

RECONSTRUCTIVE SURGERY

Mr NORMAN CAPENER (Exeter), introducing a symposium on reconstructive surgery in poliomyelitis, recalled that disability might depend on many factors which must all be borne in mind in approaching the problems of reconstruction. It was equally important that there should be a full understanding of the applied physiology of muscle and joints if the most efficient use of the remaining muscle power was to be achieved.

Soft-tissue Operations in the Lower Limb—Mr J P CAMPBELL (Nottingham) discussed the rôle of soft-tissue reconstructive operations in poliomyelitic paralysis in the foot and calf. Tendon transplants alone or as accessories to joint stabilisations were of definite value. Prerequisites to successful tendon transplantation were free passive movement in the joint to be activated, adequate power in the muscle to be transplanted, direct attachment of the transplant to bone, and a reasonably direct course of the transplant from origin to insertion.

Reconstructive Surgery in Childhood—Miss M FORRESTER-BROWN (Bath) recalled that some years ago she had pleaded for stabilisation of deformed feet early in childhood, but it had been argued against her proposal either that fusion was not obtained or that feet so stabilised did not grow. In her experience these criticisms were unfounded: for fusion was in fact obtained, and provided only the articular part of the cartilage was removed growth continued.

Subtalar Arthrodeses—Mr T T STAMM reviewed the important part played by tarsal fusion operations in stabilising paralysed and deformed feet. Any foot could be stabilised by triple tarsal fusion. Because the foot was hinged behind its centre it was usually desirable to displace the foot backwards (as in the Naughton Dunn operation) as part of the triple fusion operation, to prevent the tendency for the forefoot to drop downwards. For simple drop foot the Lambrinudi type of tarsal fusion, in which an anterior wedge is removed from the subtalar joint, was very satisfactory. Reversed drop foot or calcaneus deformity was well corrected by a reverse type of Lambrinudi procedure in which most of the bone wedge should be taken from the calcaneus. The late results in thirty-two cases of tarsal arthrodesis were presented by Mr A J DREW. From the point of view of function the results were highly satisfactory, but the appearance of the foot was often less pleasing. There was freedom from pain in 74% of cases.

Elmslie's Operation for the Calcaneus Foot—Mr J A. CHOLMELEY (Stanmore) reviewed the important features of Elmslie's operation for calcaneus deformity of the foot. The operation was done in two stages. At the first stage cavus deformity of the foot was corrected by soft-tissue stripping and talonavicular arthrodesis, and the

foot was immobilised in plaster in extreme dorsiflexion. At the second stage the posterior part of the subtalar joint was arthrodesed through a posterior approach: a longitudinal strip of the tendo achillis was attached to the back of the tibia, to give a tenodesis effect with the foot in 20° of equinus, and the calf muscles were reinforced by transfer of tibialis posterior, flexor digitorum longus, flexor hallucis longus, and peronei longus and brevis to the back of the calcaneus.

Discussion—Mr S A S MALKIN (Nottingham) said that two of the greatest problems in the reconstructive surgery of poliomyelitis were paralysis of the gluteus medius and paralysis of the quadriceps. In gluteus medius paralysis he had been dissatisfied with the results of the various tendon transfers. In quadriceps paralysis the merits of hamstring transfers had been disputed, but in his opinion they were of definite value. He did not consider that any reconstructive operation could be regarded as entirely satisfactory unless it reduced or eliminated the need for appliances.

Mr ERIC LLOYD had studied the late results in a series of cases operated on many years ago for calca deformity. In the first series the Elmslie operation had been used, in the second the reverse Lambrinudi operation. There was very little to choose between the results in the two series. He suggested that neither operation should be done in children under the age of ten years.

Mr H H LANGSTON (Winchester) felt that the best care now being given to patients in the early stage of poliomyelitis might reduce the proportion of cases requiring reconstructive operations.

Mr E S EVANS (Alton) referred to the use of lumbar ganglionectomy as a means of improving the peripheral circulation and reducing such troublesome complications as chilblains. He considered that ganglionectomy was too often been condemned because too much was expected of it. It was true that the dramatic improvement in the circulation was not maintained, the circulation never returned to a state as bad as before the operation. His technique had included removal of the second, third, and fourth lumbar ganglia. After the operation decrease of the relative shortening of the limb had been observed in one patient. He proposed to extend the operation to include the removal of the first lumbar ganglion. Through improving the circulation in the more proximal part of the limb it was possible that greater stimulation of growth might be achieved.

OTHER SUBJECTS

Research on the Transport and Multiplication of Virus—Mr KINGSLEY SANDERS (Oxford) had studied the behaviour of a virus causing encephalitis in mice, with particular reference to its transport and multiplication in the body. Since the lesions produced by the virus and certain other features of its behaviour, were closely similar to those of the virus of poliomyelitis, he believed that his researches might have a bearing on the transport and multiplication of the poliomyelitis virus itself.

Fracture-dislocation of the Foot—Mr W GISSA (Birmingham) drew attention to the risk of circulatory arrest in the foot after dislocation of the tarsometatarsal joints with multiple metatarsal fractures—the Lisfranc fracture-dislocation. He believed that the bone injury was caused by excessive rotational violence rather than by direct violence. He advocated immediate operative reduction, the first step in which should be to secure accurate reduction of the medial and middle cuneiform metatarsal joints.

Fractures of the Radial Head with Inferior Radio-ulnar Dislocation—Mr P ESSEX LOPRESTI (Birmingham) described an uncommon forearm injury of which he had observed two cases. The injury was a comminuted fracture of the head of the radius associated with upward displacement of the radius relative to the ulna, manifested at the wrist by dislocation or subluxation of the inferior radio-ulnar joint. It was caused by a force acting longitudinally in the axis of the forearm. Although this injury was uncommon its recognition was important because if the head of the radius was excised the radio-ulnar subluxation was liable to persist or increase. Reconstruction of the head of the radius after reduction of the subluxation was probably the treatment of choice.

Birmingham Type of Light Metal Elbow crutch and Walking stick—Mr F G BADGER (Birmingham) demon-

destroy *Leishmania donovani*, an organism closely resembling toxoplasma in appearance and habits

Few opportunities have arisen in this country for studying a series of cases of toxoplasmosis, and most of the information comes from SABIN and his co-workers in America. This issue contains a paper on the disease from Scotland and two from north-west England, where some of the first cases were recognised by FARGUHAM and TURNER. Dr FARGUHAM now reports the infection in binovalar twins, one having overt clinical and radiological signs, whereas the second had serum antibodies in high titre but only minimal clinical signs. Congenital defects caused by maternal rubella have also been found in one twin when the other seemed normal. We know practically nothing about the transfer of toxoplasma parasites to the foetus, but if both these infants were exposed to the infection in utero they presumably had equal chances of acquiring frank clinical toxoplasmosis. It may be that definite involvement of placental tissue always precedes invasion of the foetus, or that previous structural damages to the infection be is to gain a footing. One foetus might then be infected before the other, and the second would derive greater benefit from the rapidly developing antibodies in the maternal circulation. The pathogenesis of the congenital disease is discussed by Dr MACDONALD who attempts to reconcile the widespread subclinical infection in adults with the comparatively rare diseases which produce severe destructive lesions in the nervous tissues of the foetus. It seems reasonable to suppose that the foetus is more likely to acquire toxoplasmosis if the mother is herself infected during pregnancy, but there is no direct proof of this. The mothers of infected children often give no history of illness in pregnancy, but it is often difficult to obtain a history of illness from adults who have serological evidence of contact with the parasite. If adults carry the toxoplasma for a short time this might explain why usually only one child in a family is affected. But most other protozoa tend to persist in the tissues and it seems more likely that in subsequent pregnancies the foetus is protected by neutralising antibodies in the mother's blood, and thence in the cord blood.

Less than a dozen cases of congenital toxoplasmosis have previously been described in the British Isles, though the case reported by Dr RILEY and Dr ARNOLD recalls that the disease is not confined to one area. From the serological tests on 100 suspected cases reported by Dr MACDONALD we can gather some thing of the incidence of the disease in north-west England. Of 12 children with both chororetinitis and cerebral calcification 10 gave positive serological tests, whereas there were only 4 positives among 88 suspected children who did not have both these signs. It is unwise to select patients for laboratory investigation by hard and fast rules, but signs posts are useful in a field where there are many conditions with superficial resemblances. Moreover, as SABIN and FELDMAN* have pointed out, not all patients with chororetinitis and cerebral calcification are infected with toxoplasma. Nevertheless, this combination of signs is a useful pointer, even though subsequent laboratory confirmation is essential. MACDONALD found complement-fixing antibodies in

RHEUMATIC CARDITIS

Annotations

about 5% of normal adults, and the American results in skin tests suggest considerably higher figures for symptomless infection. Thus a positive serological test in the mother may not tell us the nature of her infant's infection, and the transfer of maternal antibody to the foetus makes positive results in the first weeks of life of doubtful significance. In seeking laboratory confirmation of a foetal clinical diagnosis, samples of serum from both mother and child should always be examined and if necessary these tests must be repeated when the child is over three months old. Manifest toxoplasmosis is uncommon, but as a cause of severe lesions in infants and one of our few indigenous protozoal diseases it should be kept in mind not only by paediatricians but by all concerned with preventive medicine.

THE pharyngitis which commonly precedes attacks and recurrences of acute rheumatic carditis in children is almost certainly due to infection by β haemolytic streptococci, and it is highly significant that when the carditis is active the serum contains precipitins to Lance fields as a substance—an anti-genic protein abundant in the cells of the group A streptococci responsible for most acute pyogenic inflammations in man. The rheumatic child deals with his throat infection in a peculiar way. Specific antibody production goes on continuously for months, whereas in uncomplicated streptococcal tonsillitis it ceases in a week or two. The streptococci he deep in the pharyngeal submucosa, and despite immunisable attempts group A streptococci have never been cultivated from the blood. Furthermore, the inflammatory reaction in the heart bears no histological resemblance to acute streptococcal inflammation and contains no streptococci. We may assume, therefore, that the rheumatic child develops a considerable degree of antibacterial immunity to the antigen locked up in the bodies of pyogenic cocci which remain unmoved deep in the pharynx, and that the carditis results from liberation into the blood of a soluble streptococcal antigen. Acute rheumatism in children follows a pathogenetic pattern which is becoming increasingly familiar: a focal infection, due to a micro-organism which never invades the blood stream, and whose chief offensive weapons are soluble endotoxins, is followed by the continuous production of anti-endotoxin antibodies and by non-bacterial inflammation of the connective tissues of a deeply placed organ or tissue. These are precisely the conditions under which such inflammation, sometimes severe, can be produced in animals. We now know that the adjuvant of the pituitary adrenocorticotrophic hormone influences not only acute rheumatic carditis but several other diseases with a similar pathogenesis, and this hormone also abolishes the tissue hypersensitiveness of the tuberculous animal to tuberculin. These facts strengthen the case for regarding acute rheumatic carditis as an example of specific hypersensitivity of the cardiac connective tissues to an antigen contained in group-A streptococci. This hypothesis would be further and greatly strengthened if certain inflammations could be produced in animals by the administration of the pituitary adrenocorticotrophic hormone together with a similar pathogenesis, and this other diseases with a similar pathogenesis, and this

spread bacterium free inflammation in the cardiac connective tissue of rabbits into which group A streptococci were repeatedly injected intradermally. Photomicrographs of lesions from all parts of the hearts of these animals resemble almost uncannily the lesion in man. This work will probably stimulate research into the precise streptococcal antigen to which the cardiac tissues of the rheumatic child are hypersensitive. We may then hope that permanent desensitisation will prove practicable.

TUBERCULOSIS THE SCOTTISH DRIVE

IN England and Wales the initial rise in the death-rate from pulmonary tuberculosis during the war was not maintained, though the incidence rose and remained high. In Scotland, however, the death rate not only rose at the start of war but continued to rise fairly steadily, mounting from 52 per 100,000 population in 1938 to 66 per 100,000 in 1948. Signs of a fall appeared last year, when the Scottish rate dropped to 59 per 100,000, and the figures for the first half of this year suggest a further improvement. But these rates remain high compared with the 1948 rate of 44 for England and Wales. Moreover, the notifications, which have remained stationary or even declined slightly in England and Wales, have risen steadily in Scotland, from 4793 in 1938 to 8427 in 1949. Mr Hector McNeil, the Secretary of State for Scotland, is anxious that the Scottish regional hospital boards should do their utmost to improve the medical and nursing services, the hospital accommodation, and the clinic and domiciliary care offered to the tuberculous. In a memorandum¹ he reminds them that cases cannot be detected early unless hospitals, outpatients, clinics, and general practitioners work together, and that early treatment depends on the provision of enough hospital beds. He does not specify the number required, but it will be remembered that the joint subcommittee² of the Scottish Central Consultants and Specialists Committee and the Tuberculosis Society of Scotland, which reported last July, suggested that 1350 additional beds are needed. The regional boards are already planning to increase as far as staffing will allow the numbers of beds for the treatment of tuberculosis in sanatoria and hospitals for infectious diseases. The Minister is also investigating the possibility of sending patients to the Swiss sanatoria as used to be done by local authorities before the National Health Service Act, but he thinks that in addition some, at least, of the general hospitals, including the teaching hospitals, should establish tuberculosis units. Both student nurses and medical students will thus get some very necessary experience of tuberculosis, though, as the memorandum points out, proper precautions must be taken to protect them against infection. The General Nursing Council have agreed to consider any alterations, required by this change, in the student nurse's curriculum.

Though this plan will present many difficulties, the Minister is convinced that it will be easier to stiff general hospital beds than to establish tuberculosis facilities elsewhere. Modern advances in treatment make it important for the chest physician to be closely associated with his colleagues in other specialties, moreover an increasing number of tuberculosis physicians are nowadays treating other diseases of the chest as well. Both the patient and his doctor need the resources of a general hospital. But the scheme does mean that special arrangements must be made for the disposal of sputum, ventilation, laundry, and X-ray screening, and, since there is no extra money to spare, expenses must be covered by cutting down on other services—always a painful process. Again, experienced chest

physicians are scarce, and the regional boards will have to consider the establishment of training appointments for young men taking up this work. In such posts they should be associated not only with the other specialists sharing in the treatment of tuberculosis (for instance, with thoracic, orthopaedic, and urogenital surgeons) but with medical officers of health dealing with prevention and aftercare, and with the resettlement services of the Ministry of Labour.

A good domiciliary service, supplementing hospital care, can reduce greatly the time patients spend in the wards and thus must of course be associated with an effective clinic service. The boards are asked to study the present distribution of clinics in their areas, decide where the chief ones should be, and arrange that they should work in association with the appropriate hospitals—not only tuberculosis hospitals but the main general and teaching hospitals. Small country clinics should be associated with outlying hospitals. The physicians responsible for the clinics should work in the hospital inpatient team and act as consultants in the domiciliary service.

These constructive proposals bear out many of those recommended by the joint subcommittee already quoted. The Minister intends to ask at intervals, about the progress of the work, and hopes that the boards will use these occasions to keep their tuberculosis services under regular review.

THE PRACTITIONER'S REMUNERATION

THE council of the Medical Practitioners' Union has been examining the profession's claim for better remuneration of general practitioners and its views are set out in a persuasively written newsletter¹. The council argues that the case (prepared by the General Medical Services Committee) for a percentage increase of remuneration, calling for another £6-7 million, would fail at arbitration, and it thinks that there would be far more chance of success for a claim limited to £5 million per annum for "removing anomalies and improving the conditions of those doctors at present underpaid." From the central fund, which, with the new £5 million, would amount to about £45 million but would vary with the number of doctors in the service, all practitioners would receive a portion of their remuneration as an "expenses factor," varying from £600 to £800 a year with the size of the practice, a further sum of up to £200 as a "length-of-service" factor and uniform capitation fees at a rate round about 12s 6d per patient. Mileage allowance, inducement payments, and the existing extra payments for additional services would be undisturbed.

Obviously before we can divide extra money we have to conquer the Treasury's reluctance to believe that we have an unanswerable claim to receive it, we have to show that this extra money is needed to fulfil promises made to the practitioners, and to make their remuneration an adequate reward for their training, skill, and load of work and responsibility. The G.M.S. Committee's case is that at least a further £7 million is essential for remuneration on the scale promised in the Spens report, and it is so sure of the soundness of its case that it does not fear arbitration. Incidentally, like the M.P.U. it believes that the central fund should be increased proportionately with increases in the number of practitioners in the service, and it has repeatedly pressed this view on the Ministry.

In resting its case for the extra millions on the present anomalies in distribution, the union overlooks the fact that redistribution is within the power of the profession itself though so far no solution acceptable to doctors

¹ Circular R.H.B. (S) (50) 27.

² Tuberculosis Service in Scotland. *Brit. med. J.* 1950 II 61.

¹ *Medical World Newsletter* Nov 10 1950. Published by the Medical Practitioners' Union, 55 Russell Square, London W.C.1.

in all parts of the country has been found which does not involve the provision of new money. In contrast with the M.P.'s proposals, the Conference of Local Medical Committees agreed that the supplementary millions should be used to increase the capitation fee on the first 1000 patients. The sum of nearly £7 million which is being claimed would provide about £250 a year extra for each patient—perhaps a little more for some if fewer fixed annual payments were needed in some areas. Admittedly this gives an all round increase not confined to the small list doctor. But it is an agreed solution which all doctors are willing to accept, and it is the only plan yet agreed which will at the same time help the doctors in the small list areas and encourage the taking of assistants into partnership in the busier practices, so adjusting two of the most pressing anomalies. Would the M.P. Council still recommend their new system of remuneration if the Treasury refused to add to the central fund? Before the start of the service the profession rejected the idea of a universally applicable portion of remuneration unrelated to the number of patients. Two years' experience may have induced different situations in which such a reform cannot (in the absence of new money) be achieved without a much greater disturbance of earnings than would have been caused earlier.

DAWSON OF PENN

Official biographies are usually rather dull, and, because they tend to omit anything not altogether creditable, slightly misleading. The new biography of Lord Dawson¹ is much more satisfactory. There is a good deal of detail which is not really necessary about the changes in England and in medicine during the eighty years of his life, but many of the character sketches are intensely interesting. To many readers the most astonishing thing about Lord Dawson himself will be the amount he achieved. If he had shut himself up in his bedroom like Florence Nightingale and attended to nothing but public policy, the record would, perhaps, not have been so surprising, but it is impressive when one remembers that it was all done in addition to a busy private practice and hospital work, teaching, personal attendance on committees, and endless contacts with people. It is always worth considering what made a man great: the differences between a great man and the average are, after all, smaller than is often supposed. In Lord Dawson the driving force—and without driving force the greatest abilities can, and often do, come to nothing—seems to have been compounded of ambition and a strong religious sense of obligation to other people as individuals. The origin of ambition is usually obscure Dawson's sense of obligation derived from the intensely religious, though unsectarian, atmosphere of the period of his development—it was the time of Huxley and the other Bible saturated and agnostic moralists. The attention to the individual rather than to the abstract cause was part of the triumphant liberalism of the same historical epoch. Another derivation of liberalism was his reiterated insistence on the principle, "never discourage the bad, always encourage the good."

Of the qualities by which Dawson achieved success the first was his conscious application of method. He always said that he did one thing at a time, which means that he trained himself to give his whole attention to the matter in hand. People who do not do this can remember faces but not names, and that they have complaint that they have a poor (musical) memory, that they was his systematic use of holidays and the equally systematic way in which he distributed his holiday time. Dawson of Penn. By FRANCIS WATSON. London: Chatto and

The second important quality was his "uncanny capacity for anticipating public or sectional reactions to any proposed measure," "his instinct for striking the right note at the right moment." Possibly related to this was the observation that "he predicted with some precision where shortfalls would be felt. He would have been worth his weight in gold to a black marketeer." It was this understanding of what was practicable and what was not which both made him so successful in his campaigns and led to the misconception that he was not a crusader. In fact, as this biography shows, he embarked on many crusades, to some of which he kept returning and some of which he never brought to a satisfactory conclusion. He was always prepared, as in the case of health centres, to await the favourable moment. Another of his qualities was his skill in choosing men. This was not a mysterious flart, but the result of careful investigation and thought. It was related to his unusual helpfulness to patients in such matters as choosing the best resort for convalescence. A useful instance of his capacity for team work and organisation described in the book is his investigations on jaundice in the 1914 war. The detail given of this story is justified because detractors used wrongly to say that Dawson had stolen the work of younger men by virtue of his military rank. The last quality which was essential to Dawson's success was his capacity for hard work. This is almost indispensable for success, but as a rule it is the result of brute physical stamina. This was not true of Dawson. He was often physically below par. His hard work was the result of determination combined with a methodical turning of his own physical resources. This nursing extended beyond orthodox methods to include such beliefs as the value of letting his armel lie on his feet in the car, on the grounds that "so long as the feet were kept warm one would not have headaches." Little troubles like this in the great physician were endearing. Mr Watson deals at length with the still rather too personal question of Lord Dawson's religion. But it as interesting that he tended, not to the agnostic stoicism of his era, but to definite membership of the Church of England, in the sense of the comprehensive church, rather than the exclusive one of creeds and articles.

W H O, F A O AND NUTRITION

Two United Nations agencies, W H O and the Food and Agriculture Organisation (F.A.O.), both have nutrition sections, and a joint expert committee was set up to coordinate them. This met for the first time in Geneva a year ago, and the report of its first meeting has now been published. In brief, it recommended the continuance of established policies—notably the coordination of technical knowledge by the organisation of regional nutritional conferences, the publication of technical memoranda, and the promotion of education, primarily by the award of travelling fellowships. In these ventures F.A.O. will lay emphasis on nutrition in relation to the production, distribution, and consumption of food, in W H O emphasis will be on nutrition in relation to the maintenance of health and the prevention of disease. In these fields both F.A.O. and W H O have already proved their ability, and we can look forward to bearing fresh accounts of good work. A new recommendation put forward by the committee was that W H O should undertake field research, and endemic goitre and kwashiorkor were considered suitable subjects for investigation. This would be an important new departure. The question whether U.N. Joint F.A.O./W H O Expert Committee on Nutrition Report on the First Session W H O Technical Report Series no. 16 Geneva June 1950 Obtainable from H.M. Stationery Office

is a suitable organisation for initiating and planning new research has already been debated at length.² Such projects are bound to meet two difficulties. The first would be to recruit first class investigators, at a time when almost all countries are short of scientists of the front rank, it would be hard to collect a good international team without seriously weakening national research services. Secondly, an international research group would have to be very circumspect if it was to maintain harmonious relations with research workers and officials in the country in which it was operating. True, this is no fundamental objection, but it is easy to visualise real difficulties arising in practice. Certainly it would not be easy for F.A.O. and W.H.O., as discoverers of new knowledge, to repeat the successes which they have already achieved as coördinators of research and as educationists.

RUSSIAN IMPRESSIONS

In the years before the war a good many British doctors visited Soviet Russia and found the experience exhilarating. The general conclusion drawn from their reports was that in those days the Russians were mostly behind us in medical research and in the higher flights of diagnosis and treatment, but often ahead of us in arranging for the benefits of medicine to reach the people. Immense needs, and corresponding scarcities, had obliged the planners of Soviet medicine to create what was primarily a utility service, but they hoped that, as prosperity increased, its quality would steadily rise. Whether, despite war and preparations for war, the medical services have in fact improved, we do not know, for unhappily the Russian authorities have discontinued their policy of demonstrating their achievements to all comers. Nevertheless it seems that the façade, at least, of Soviet medicine is still as impressive as ever, and it is most interesting to have the comments of a colleague who has just seen it for the first time. Dr. Nora Johns, who was Labour candidate for Kingston upon Thames at the last General Election, has just spent three weeks in Russia as one of a women's delegation invited by the Anti Fascist Women's Committee of Moscow. As well as Moscow, she visited Kiev, Stalingrad, and the Crimea, and on Nov. 8, five days after her return, she reported her observations to a meeting of the Socialist Medical Association, who had nominated her as their delegate.

In the cities, Dr. Johns found, general medical services are provided through health centres, open night and day, serving 10 000-50 000 people, according to the density of the population. In these centres the family doctor and the specialist work side by side, with equal pay and equal status: the former is responsible for his 1200 odd patients at home and in hospital, and the specialist is called in as an adviser when required. The centre provides a wide range of diagnostic facilities, as well as physiotherapy, and dental and eye services. Attendance is based on an appointment system and the practitioners spent about 2 hours a day in the centre and about 4 hours visiting—at the rate of four visits an hour. Tuberculosis and infectious diseases have their own services distinct from the health centres, and tuberculosis is discovered early (Dr. Johns was told) by means of the biannual examination, including radiography, of every man, woman and child in the country. She was informed that the tuberculous are admitted to a sanatorium, or to special wards in general hospitals, as soon as they are diagnosed.

There is, it seems, no staffing problem in the Soviet Union: (1) because for 3 years after qualifying, young doctors and nurses can be directed to any place where they are needed, (2) because the 6 hour shift system

enables everybody to live out, and (3) because the number trained is based on the number needed. Though the average doctor earns less than a shopkeeper ("it was a shock to learn the true status of doctors in society"), there is no shortage of entrants to the profession—perhaps because every doctor has the chance to become a research worker with a high salary and exalted status, such research usually being related to some immediate industrial or social problem. The medical services of industry have top priority. Each factory, large shop, or plant is responsible for all its own social and medical services, which include a crèche, a kindergarten, a rest home, and a community centre, as well as first aid stations and a complete health centre. No child under 16 may enter industry, and overtime is forbidden for those under 18 and for pregnant and nursing women, the latter are allowed time off (with pay) to feed their babies, and so are mothers who have sick children at home or in hospital. There are no proprietary medicines, but the State is building up a pharmaceutical industry which is already exporting some of its products. Antibiotics appear now to be plentiful, but Russians speak with appreciation of the drugs received from their Western allies during the war.

In reply to questions, Dr. Johns said that her medical hosts would not admit the existence of neurosis or delinquency among their people. She was unable to present any all Russia statistics (mortality, morbidity, doctor/patient ratio, &c.) because they are not published, "for security reasons", and she had learnt nothing about the care of the chronic sick, and of congenitally deformed or defective children. She had formed the impression that specialists and research workers were well versed in the latest British and American work, and she pointed out that the English language was taught in all Russian schools. It was true that her visit had been in the nature of a conducted tour, but when she fell out of the party and wandered alone her observations only confirmed her previous impressions. She had made a particular study of the people's diet, and she produced canteen menus and other data to support her contention that the Russian worker was better fed than his British counterpart. All in all, the British delegation left with the conviction that the lives and feelings of the Soviet people were being completely misrepresented by British newspapers and speakers.

CYSTS OF THE JAWS

THE radiological diagnosis of cysts and cyst-like tumours of the jaws is a highly specialised subject to which few radiologists have been prepared to pay much attention. Though Worth and some others have established criteria which enable a correct diagnosis to be made in a high proportion of cases, the reports returned in other than special departments are often of little value and sometimes surprising.

Even those who have made some study of these cysts will find interest in Sonesson's analysis of some two hundred cases verified by pathological examination¹, for he provides a reliable guide to the radiological findings and his illustrations form a good reference collection. Perhaps what is chiefly debatable about his work is the validity of the pathological criteria. One may, for example, question the extent to which the presence of a cyst lined with stratified squamous epithelium in continuity with an adamantinoma proves the origin of the latter from one of the simple odontogenic cysts. And the classification and pathological identification of fibro-osseous and myxomatous changes in the jaws is so difficult and so little agreed that a discussion of the radiological appearances of different named conditions must at present be somewhat unsatisfactory.

PHYSICAL AND BIOLOGICAL EFFECTS
OF ATOMIC EXPLOSIONS

FROM A CORRESPONDENT

The most comprehensive and authoritative account

of atomic bomb explosions so far released to the public has lately been published in a book, *The Effects of Atomic Weapons*,¹ compiled for the United States Atomic Energy Commission and Department of Defense by the staff of the Commission's Los Alamos Scientific Laboratory, University of California, and an impressive body of other American experts. The book is intended to be "a source of scientific information for technical personnel," and it deals mostly with the physics of the explosion of "nominal" atomic bombs—i.e., bombs similar to those dropped in Japan and tested at Bikini. Much material that has hitherto been "secure" is included. No information is given about the hydrogen bomb, but there are extensive though often theoretical calculations of various physical effects, based on the explosion of a bomb equivalent to 20,000 tons of T.N.T. The discussions of physical phenomena include sections on their biological and medical implications, and there is a chapter on the protection of personnel. The object of this article is to summarise the descriptions given of various types of atomic explosions and to interpret the biological data in terms of human suffering and medical defence.

GENERAL DESCRIPTION OF ATOMIC EXPLOSIONS

Uranium²³⁵ and plutonium²³⁹ usually decay slowly, sometimes with the release of particles called neutrons. When two masses of fissionable atoms such as these are suddenly brought close together, the neutrons being given off by one mass are augmented by those from the other. If the two masses are of critical size, the neutrons reach such an intensity that a chain reaction starts, whereby the neutrons break down uranium or plutonium, with the release of more neutrons, further fission of uranium or plutonium, and so on. This chain reaction releases large quantities of energy and leaves smaller atoms (fission products) behind. The total mass of the fission products is less than the original mass of uranium or plutonium, the difference having been turned into energy.

At the instant of fission a large number of neutrons and large amounts of gamma (electromagnetic) radiation are emitted. The latter is called the prompt gamma radiation, because the fission products include radioactive isotopes, the bulk of which break down more slowly over the first minute, also liberating (delayed) gamma radiation as they do so. The energy released by atomic fission, as in atomic bombs, raises the temperature of the bomb casing and the fission products to over 1,000,000°C by 0.000001 sec after the start of the explosion. This energy is dispersed in various ways, depending on the medium in which the bomb is exploded. Thus the explosions in air, under water, or underground differ in their effects on human beings and material.

Bomb Bursting in Air

The results of an air burst normal atomic bomb can now be described more precisely and in greater detail.

The Effects of Atomic Weapons Board of Editors Dr J O Hirschfelder professor of chemistry University of Wisconsin, Lieut. Colonel David B Parker U S Army General Staff, Arnold Kravitch physicist to Atomic Energy Commission, and Dr Ralph Carlisle Smith assistant director of Los Alamos Scientific Laboratory Executive Editor For Samuel Glasstone Washington D C The Combat Forces Press 1950 Pp 450 \$3 London McGraw Hill 25s 6d

When fission occurred in the air burst atomic bomb at Bikini, most of the prompt gamma radiation released is believed to have been absorbed by the bomb casing. Immediately (0.000001 sec) after fission there was a small core of intensely hot material less than 30 ft in radius at the site of the explosion. At this time the central mass was so hot (1,000,000°C) that it emitted electromagnetic radiations of extremely short wave length which hardly penetrated the air at all. Thus the atmosphere prevented the loss of much energy by radiation from the explosion at this stage. However, energy was probably lost in the following three ways.

(1) The neutrons released by fission passed through the disintegrating bomb casing and through 2000 ft of air in a second, by which time and at which range almost all of them had been absorbed or had lost their energy. (2) The sudden rise of temperature at the bomb caused a rapid expansion of the surrounding atmosphere which was propagated through the elastic air as a shock "front". In the very early stages after the explosion the compression force of this shock front was sufficient to heat the atmosphere to incandescence. After 0.0001 sec the air at the shock front had a temperature of about 300,000°C. As the shock wave spread outwards its energy per unit area diminished and the temperature to which it heated the air therefore diminished. After 0.01 sec the air, though still incandescent, had a temperature of some 2000°C.

Meanwhile, behind the expanding incandescent shock front the fireball containing the fission products, which were still releasing gamma radiation, was expanding. As it did so, the surface temperature of the fireball fell, so the radiations it emitted were of longer wave length, which could penetrate the atmosphere more easily, thus the cooling continued more rapidly, not only because the fireball was expanding and so involving more atmospheric molecules but also because of heat losses by radiation. The radius of the fireball was about 45 ft at 0.0001 sec, about 100 ft at 0.001 sec, and approached its maximum of 450 ft at 0.01 sec. At this time its surface began to take over the role of thermal radiator, for the shock wave was no longer making the surrounding air incandescent. The temperature of the radiating surface of the fireball is reputed to have risen to about 7500°C by 0.3 sec from the start of the explosion, after which it began to fall, reaching 5000°C at 1.0 sec.

Thus a second after the explosion there was a central fireball about 450 ft in radius, cooling, and raising upwards because of its heat. It had already released almost all its ultraviolet light and most of its thermal radiation (white light and infra red radiation), and the fission products had liberated half their total gamma radiation. Furthermore, the explosion had propagated neutrons out to 600–700 yards, and by this time these particles could only have any further effects through radioactivity which they had induced. Finally, by this time the blast front had reached about 800 yards, and was being followed by a suction wave. This suction wave was responsible for the next dramatic event. The expansion of the atmosphere led to condensation of moisture—the "Wilson cloud chamber effect". This cloud seems to have been formed about 1.5 sec after the explosion at Bikini, and at a distance of about 800 yards. By absorbing thermal radiation, the cloud would probably have protected persons beyond it from the small residual quantity of emitted thermal radiation which the fireball subsequently released. After 10 sec the fireball had risen 1500 ft and had given off 80% of its total gamma radiation. The greater its contents condensed, forming the famous mushroom

cloud, which was slowly dispersed by wind. The residual radioactive material in this cloud returned to the earth many miles away in rain—the so called “fall out”

Bomb Bursting Under Water

A bomb was detonated below the surface of the Bikini lagoon, which was 200 ft deep.

In the very early stages after the underwater explosion at Bikini atomic fission must have formed a fireball of intensely hot material. This started a shock wave through the water and forced water upwards as a dome of spray. The fireball, which rose through the water, had become a bubble of superheated steam before it reached the surface. When this bubble impinged on the atmosphere it initiated an air shock front which travelled outwards and formed a Wilson cloud round the explosion in much the same way as the shock wave from an air burst bomb. Within this cloud, water was being thrown upwards by the detonation in the form of a hollow column, called the “plume,” surmounted by the rising mushroom cloud of steam and fission products from the original ball of fire. The plume probably reached a maximum height of 8000 ft and was about 2000 ft across. Its walls were about 300 ft thick and were formed of water droplets. After 10 sec the water droplets, containing highly radioactive material, began to fall back towards the lagoon, producing a mist, the “base surge,” resembling the one at the foot of Niagara Falls. This mist consisted at first of a blanket of fog about 100 ft high at the base of the plume. It spread outwards from the plume and moved rapidly over the lagoon, reaching a distance of 8000 ft in about 3 minutes.

For a while the mushroom cloud above continued to rise, but then it too fell back towards the lagoon. A minute after the detonation the first particles fell into the base surge, and by 2½ minutes almost all had fallen back into this fog bank. Most of the material from the mushroom cloud was widely scattered by the explosion and fell into a ring with an inner radius of about 2000 ft and an outer radius of about 3000 ft.

At 3 minutes after the explosion, therefore, the site was surrounded by a cloudy ring of radioactive water, some 1800 ft high, and with an outside radius of 8000 ft. This base surge then began to rise, until at 4½ minutes it was 1500 ft above sea level. Shortly afterwards radioactive rain began to fall from it and continued to do so for an hour as the cloud moved down wind.

This description suggests that, in the initial stages of the explosion, nearly all the energy of the bomb was imparted to the water. Thus the neutrons and gamma radiation released at fission were captured by the sea water and formed radioactive substances in it. The fission products were dissolved in the steam of the gas bubble. The shock wave imparted to the water, and the gases in the bubble, were responsible for pressing up the dome of spray which became the mushroom cloud and also the hollow cylinder of radioactive material called the plume. Later the plume and the mushroom cloud fell back towards the lagoon as droplets and formed the dangerous base surge, which spread out over a large area. The fission products in the mushroom fell into the base surge, and the whole moved down wind as a cloud, from which radioactive rain fell for nearly an hour.

The base surge might have different characteristics from those seen at Bikini in other weather conditions, and detonation at greater depths would alter the effects of the explosion.

Bomb Bursting Underground

No observations on actual underground atomic bomb explosions are reported in the book. The effects would

depend on the soil characteristics and rock formations, but some general predictions can be made. Soil and rock would be displaced by the sudden expansion of the fireball, and if the bomb was detonated 50 ft below the surface in ordinary soil, a crater 800 ft in diameter and 100 ft deep would be produced. A severe shock wave would be imparted to the surrounding ground and almost all buildings would be destroyed up to 1000 yards from the explosion. A good deal of radioactive dust containing dangerous radioactive isotopes would be liberated from the crater. This dust would rise from the ground and be disseminated by wind and create a hazard wherever it fell. However, the crater would screen people on the surface from neutrons and much of the gamma and thermal radiations in the same way as the water did in the Bikini lagoon.

Conclusions

It will be seen that atomic bombs will have widely different effects according to whether they are detonated in air, in water, or underground, and their effects will also depend on such environmental factors as the weather, the salinity of the water, and the nature of the soil and rocks. The energy of the explosion is most rapidly dissipated when the bomb bursts in the air, whereas underwater and underground explosions release dangerous radioactive products which are scattered on water or dust particles and only slowly dispersed, mainly by the wind.

DETAILS OF AIR BURST EXPLOSION

The effects of atomic bombs must be studied in greater detail if the medical hazards are to be grasped. The book discusses the various effects separately, giving the ranges for each effect, its limits after 1 sec, the changes produced by the weather, and, finally and ominously, the probable increase in ranges with more efficient weapons.

Blast Wave

The blast wave from an air burst atomic bomb moves outwards somewhat faster than sound. At Bikini the blast front reached 800 yards in 1 sec, 1300 yards in 2 sec, and so on. As the blast front moves outwards, the pressure it imparts to the air diminishes. This is shown in fig 1, together with the probable effects of the blast front on buildings at the various ranges.

From the point of view of human survival the blast wave has one favourable attribute—it takes time to

Fig 1—Peak pressure and speed of and expected destruction by blast wave of atomic bomb at various ranges.

The discussions of physical phenomena include sections on their biological and medical implications, and there is a chapter on the protection of personnel. The object of this article is to summarise the descriptions given of various types of atomic explosions and to interpret the biological data in terms of human suffering and medical defence.

GENERAL DESCRIPTION OF ATOMIC EXPLOSIONS

Uranium²³⁵ and plutonium²³⁹ usually decay slowly, sometimes with the release of particles called neutrons. When two masses of fissionable atoms such as these are suddenly brought close together, the neutrons being given off by one mass are augmented by those from the other.

If the two masses are of critical size, the neutrons reach such an intensity that a chain reaction starts, whereby the neutrons break down uranium or plutonium, with the release of more neutrons, further fission of uranium or plutonium, and so on. This chain reaction releases large quantities of energy and leaves smaller atoms (fission products) behind. The total mass of the fission products is less than the original mass of uranium or plutonium, the difference having been turned into energy.

At the instant of fission a large number of neutrons and large amounts of gamma (electromagnetic) radiation are emitted. The latter is called the prompt gamma radiation, because the fission products include radioactive isotopes, the bulk of which break down more slowly over the first minute, also liberating (delayed) gamma radiation as they do so.

The energy released by atomic fission, as in atomic bombs, raises the temperature of the bomb casing and the fission products to over 1,000,000°C by 0.000001 sec after the start of the explosion. This energy is dispersed in various ways, depending on the medium in which the bomb is exploded. Thus the explosions in air, under water, or underground differ in their effects on human beings and material.

Bomb Bursting in Air

The results of an air burst nominal atomic bomb can now be described more precisely and in greater detail.

¹ The Effects of Atomic Weapons. Board of Editors: Dr J. O. Hirschfelder, professor of chemistry, University of Wisconsin; Lt. Col. David B. Parker of U.S. Army General Staff; Arnold Kramish, physicist to Atomic Energy Commission; and Dr. Ralph Carlisle Smith, executive director of Los Alamos Laboratory, Executive Editor. The Combat Forces Press, 156 Pp. 1950.

When fission occurred in the air burst atomic bomb at Bikini, most of the prompt gamma radiation released is believed to have been absorbed by the bomb casing. Immediately (0.000001 sec) after fission there was a small core of intensely hot material less than 30 ft in radius at the site of the explosion. At this time the central mass was so hot (1,000,000°C) that it emitted electromagnetic radiations of extremely short wave length which hardly penetrated the air at all. Thus the atmosphere prevented the loss of much energy by radiation from the explosion at this stage. However, energy was probably lost in the following three ways.

(1) The neutrons released by fission passed through the disintegrating bomb casing and although 2000 ft of air in a second, by which time and at which range almost all of them had been absorbed or had lost their energy.

(2) The sudden rise of temperature at the bomb caused a rapid expansion of the surrounding atmosphere which was propagated through the elastic air as a shock "front". In the very early stages after the explosion the compression force of this shock front was sufficient to heat the atmosphere to incandescence. After 0.0001 sec the air at the shock front had a temperature of about 300,000°C. As the shock wave spread outwards its energy per unit area diminished, and the temperature to which it heated the air therefore diminished, so after 0.01 sec the air, though still incandescent, had a temperature of some 2000°C.

(3) Energy was probably lost in the form of gamma radiation given off by the disintegration of fission products.

Meanwhile, behind the expanding incandescent shock front the fireball containing the fission products, which were still releasing gamma radiation, was expanding because of its heating effect on the atmosphere. As it did so, the surface temperature of the fireball fell, so the radiations it emitted were of longer wave length, which could penetrate the atmosphere more easily, thus the cooling continued more rapidly, not only because the fireball was expanding and so involving more atmospheric molecules but also because of heat losses by radiation. The radius of the fireball was about 45 ft at 0.0001 sec, about 100 ft at 0.001 sec, and approached its maximum of 450 ft at 0.01 sec. At this time its surface began to take over the role of thermal radiator, for the shock wave was no longer making the surrounding air incandescent. The temperature of the radiating surface of the fireball is reputed to have risen to about 7500°C by 0.3 sec from the start of the explosion, after which it began to fall, reaching 5000°C at 1.0 sec.

Thus a second after the explosion there was a central fireball about 450 ft in radius, cooling, and rising upwards because of its heat. It had already released almost all its ultraviolet light and most of its thermal radiation (white light and infra red radiation), and the fission products had liberated half their total gamma radiation out to 600–700 yards, and by this time these neutrons could only have any further effects through radioactivity which they had induced. Finally, by this time the blast front had reached about 800 yards, and was being followed by a suction wave.

This suction wave was responsible for the next dramatic event. The expansion of the atmosphere led to condensation of moisture—the "Wilson cloud chamber effect". This cloud seems to have been formed about 1.5 sec after the explosion at Bikini, and at a distance of about 800 yards. By absorbing thermal radiation, the cloud would probably have protected persons beyond it from the small residual quantity of thermal radiation which the fireball subsequently emitted.

After 10 sec the fireball had risen 1500 ft and had given off 80% of its total gamma radiation. Theoretically its contents condensed, forming the famous mushroom

Fig. 3—Total heat flux at various ranges from air-burst atomic bomb. Interrupted line shows doses received in one second

descent by the blast wave in the very early stages, and later from the fireball

About 70% of the total thermal radiation is emitted in the first second (interrupted line in fig 3). When these radiations are absorbed by inanimate or living matter their energy is dissipated as heat. Since the total doses received at various ranges may not convey much to the average reader the effects which these doses would have on various types of material are also indicated in fig 3.

The propagation of thermal radiation depends on its attenuation by the atmosphere, hence, as the visibility diminishes, less thermal energy passes through the air. This is important because it will be seen from fig 3 that thermal injury to the skin has a very long range. On a foggy day the range of thermal injury may be reduced by as much as 1500 yards. The long ranges of thermal action in clear weather are presumably of more concern in America than in Great Britain.

The effects on various types of material shown in fig 3 are based on results obtained at the Brooklyn Navy Yard. The ranges cited fit fairly well with the actual observations in the Japanese attacks, but it is not clear how the laboratory experiments in Brooklyn were conducted and whether the spectrum of the laboratory radiation was the same as that of an atomic bomb, which is fairly difficult to simulate.

Protection from thermal radiation is afforded by non-inflammable structures (air-raid shelters or houses) and by non-inflammable thick clothes. The ignition ranges for heavy paper and light-weight fabrics given in fig 3 support the view that they are not good protection despite the contrary opinions sometimes quoted.²

2. The Home Office Manual, in its chapter on Heat Flash (p. 13) says "even clothing though it may itself become ignited, affords some degree of protection for the skin underneath, particularly if not in close contact with the body and especially if of a light rather than a dark colour. This colour differentiation only applies, however, at distances where the heat intensity has fallen below that which would fire the fabric as a whole." Atomic Warfare Manual of Basic Training. Home Office Pamphlet no. 6. London, 1950. vol. II p. 19.

Whatever errors may have arisen in the laboratory observations referred to above, there is no doubt that in Japan clothes caught fire as far as 1600 yards from the explosion, and that skin was burnt at 4000 yards. Since clothes caught fire beyond the range of fatal gamma radiation, it is certain that paper would have done so. The Japanese were burnt by contact with their clothing heated by the bomb blast at ranges up to 2000 yards, and they would have been burnt through paper at greater ranges.

The ranges of thermal injury would be extended by 500-1000 yards if the energy of the bomb were doubled. This would offset the protective action of our damp climate in Britain.

The Fall Out

About half the radioactivity in the mushroom cloud is believed to fall back to the ground in the first twenty hours after the explosion. The prevailing winds would scatter these particles widely and radiation from this source would probably not be a serious hazard unless heavy rain fell soon after the explosion when the radioactive particles might be washed down in dangerous concentrations.

The remaining half of the radioactivity in the mushroom cloud is contained in particles so small that they remain a very long time in the air. If a vast number of bombs were exploded these particles might possibly endanger all forms of life on the earth, but for this to happen something like 755,000 bombs would have to be exploded simultaneously.

Summary

An air-burst atomic bomb of the type dropped in Japan will completely devastate a central zone about 1000 yards in radius, and people in this zone will have little chance of survival. In an intermediate zone buildings will suffer moderate devastation and in an outer zone they will be less severely damaged. In both these zones burns will occur in people exposed to thermal irradiation.

MEDICAL IMPLICATIONS OF THE DATA ON AIR-BURST BOMBS

The American writers discuss very fully the effects of gamma radiation but they say little about other injuries. An attempt has therefore been made to obtain a more general view of the likely effects on human beings and to determine the value of defensive measures in reducing the number of casualties.

What would be the effects of an atomic bomb exploded in the air over a British city without warning as might happen in a sneak raid or if the bomb could be propelled by rockets? The results would be similar to but by no means identical with those seen in the bombing of Japan. It is possible to estimate roughly what types of injury would be caused at various distances from the explosion and the number of different sorts of casualties which might be expected.

Flash-burns

Apart from the central zone, 1000 yards in radius, where most people would be killed flash burns of the exposed skin could occur over about 16 sq miles. Towards the periphery of this area the heat would only be sufficient to cause shallow second-degree burns. Within about 3500 yards of the explosion third degree burns would occur where the radiation fell fully (normal incidence), whereas radiation falling at a glancing angle would cause shallower burns.

In Japan there was nothing mysterious about the flash burns reported. The radiant heat (not gamma radiation) falling on the skin heated it very rapidly, and this heating together with any photochemical effects from ultraviolet radiation, probably injured the superficial

Hence some evasive action could be taken by people outside the central zone, which is rapidly and completely devastated. However, a blast wave may cause injury or burial from falling masonry and lacera-
tion from flying glass at very great ranges, and in the central zone it may start fires as a result of the collapse of buildings.
Protection may be achieved by strengthening buildings and windows and by building blast screens.
The range of blast effects would be much greater if atomic bombs became more efficient. Doubling their TNT equivalent might extend the range by 500-1000 yards.

Neutrons

Neutrons are particles of energy carrying no electrical charge. They are absorbed by light materials, but tend to pass through heavy ones. This anomaly is explained as follows. When a neutron hits a light atomic nucleus its energy is shared between the two, so the neutron loses energy. On the other hand, when a neutron hits a heavy atom it "bounces off" without losing energy.

Neutrons injure by inducing radioactivity and by removing electrons in their path, so causing ionisation and chemical disruption in biological systems. As neutrons pass through the relatively light molecules of the air they lose energy, there were about ten times as many slow low energy neutrons (1 MeV) as fast high-energy neutrons (3 MeV) at large distances from the burst bomb at Bikini. Unfortunately, slow neutrons are a more serious biological hazard than fast ones because they are more likely to be trapped in the body.

By 1 sec after the explosion of an air burst bomb all its neutrons would be dispersed, so there would be little opportunity for evasive action. Protection from neutrons is very difficult. Reducing their energy by interposing concrete may convert fast neutrons into slow neutrons and so make them more lethal. Concrete containing iron oxide ore would provide better protection. It must be remembered that the neutrons

Fig 2—Total doses of gamma radiation at various ranges from air burst atomic bomb. Interrupted line shows ranges received in one second.

reaching any particular point will be moving (bouncing) in every direction, so if a shelter is to be effective it must be completely enveloping.
The range of lethality from direct exposure to the neutrons is estimated at about 600-800 yards. Doubling the bomb's TNT equivalent would extend this range by some 100 yards.

Gamma Radiation

Gamma radiation is an electromagnetic radiation of shorter wave length than light and ultraviolet radiation. It is propagated at the speed of light. It was emitted by the fission products of the air burst bomb at Bikini, mainly during the first minute after the explosion, 50% being released in the first second. The total doses which reached the ground at different ranges are shown in fig 2, in which the interrupted line marks the dose reaching the ground by the end of the first second, and therefore indicates the possibility of evasive action.

Gamma radiation injures biological systems by disrupting electronic and so inducing ionisation and chemical dislocation.
The probable doses of gamma radiation from an atomic bomb for fatality and illness are shown in fig 2 to indicate the ranges at which death directly exposed to sickness may be expected in people directly exposed to the bomb. The results cited are based on direct experimental measurements of the total dose, but we are not told what are the respective energies (voltages) of the gamma radiation emitted. This is important because the ionising effects of these radiations when they impinge on living organisms depend on the energy (penetration) of the radiations.

Protection from gamma radiation is afforded by heavy materials. Thus 24 in of concrete would protect human beings fairly well to within 1000 yards from the bomb (dose reduced to 100 r), but 36 in would be needed to prevent radiation sickness completely at this range (dose reduced to 25 r). Some contend that even 25 r may have severe genetic effects, and if this is true the long term consequences of atomic warfare may be even more serious than its immediate effects.
The transmission of gamma radiation through the atmosphere is unlikely to be much altered by weather conditions. It is reassuring to find that its range would not be greatly increased if atomic bombs were more efficient. Doubling the energy of the bomb would increase the lethal range by about 100 yards.

Ultraviolet Radiation

Ultraviolet radiation (U V R) is electromagnetic radiation with a wave length longer than gamma radiation but shorter than visible light.
The question arises whether this radiation would be an important cause of injury. In the earliest phases of an atomic bomb explosion a good deal of U V R is undoubtedly emitted, but these phases last less than 0.01 sec, and U V R is heavily absorbed by the atmosphere. On the other hand, owing to its photochemical action on the skin, U V R can produce burns at very low dosages. The American writers find by calculation that U V R from an air burst bomb would not be a serious biological hazard. No experimental measurements are given to support these calculations, but it seems probable that the effects of U V R would be swamped by those of thermal radiations which have a much greater range and power of penetrating human skin.
Visible and Infra red (Thermal) Radiations
The electromagnetic radiations in the visible and infra-red parts of the spectrum are usually referred to together as the thermal radiation from the air burst atomic bomb. They are emitted from the air heated to incan-

Fig 4—Surviving casualties from air-burst atomic bomb attack on unwarned community. Area of each block approximately equals area from which casualties would arise and therefore shows rough proportions of various types of casualty. A, injuries to persons out of doors directly exposed to explosion. B, injuries to persons out of doors but screened by buildings from explosion. C, injuries to persons indoors.

British city. Thus injuries from gamma radiation are important from the medical point of view for several reasons.

First, it must be clearly grasped that the total number of gamma-radiation casualties would be too large to be ignored, there would probably be several thousands in an attack against an unwarned community. However, the onset of radiation illness is more and more delayed as the severity diminishes, hence there would be spacing of cases in time—an advantage to hard-pressed medical services.

Unfortunately, gamma-radiation illness is an unknown clinical entity in this country, which places both physician and patient at considerable disadvantages. A good deal has been written about radiation sickness in Japan.³ A summary of the clinical symptoms of radiation sickness, and a description of its pathology, are given in the book. The authors explain that high doses of gamma radiation (600 r or more) were lethal in Japan. The victims vomited after an hour or two, and then had a few days free from symptoms. Before the end of the first week, however their white-cell counts had fallen to below 2000 per c.mm., and they began to get diarrhoea, vomiting, inflammation of the mouth and throat fever, and rapid emaciation, leading to death in the second week or earlier from a disease characterized by overwhelming infection and toxemia.

Victims who received the median lethal dose of 400 r were nauseated and vomited after one or two hours. They then had no definite symptoms for about two weeks. Thereafter they showed epilation, loss of appetite, fever, severe throat infections, anaemia, petechiae, and rapid emaciation during the next two weeks. Half the patients receiving this dose of radiation died and the others had a protracted convalescence, with gradual recovery from their blood dyscrasias and infections.

Victims who received much lower doses 100–400 r had a long latent period without symptoms lasting

about three weeks. Their course was then similar to, but less hectic than that of those receiving 400 r, and their mortality-rate was much lower.

There is as yet no evidence of a specific therapy for radiation illness, and little likelihood of such an advance in the near future. Further, when the patients become such diagnosis and observation of the course of the disease demands a good deal of laboratory work, especially blood-counts. Supportive treatment (blood-transfusions for anaemia and leucopenia, antibiotics for infections) is required in very large quantities and is consequently very expensive. There is also the very important point that the physician may have to decide to turn his back on people who have received high doses, leaving them as helpless cases although they may not appear very ill at the time. On the other hand, he may be confronted with a large number of people who may believe they have radiation sickness but have not. Finally, it is very likely that the course of radiation sickness would be aggravated by other injuries.

It will be seen that at very short ranges (less than 600 yards), most persons would probably be killed outright by the blast wave, by neutrons, which also produce radiation sickness, by gamma radiation, by heat, or, if indoors, by collapse of buildings.

The numbers of patients that survive the explosion, and the types of casualties seen, are shown in fig 4.

PROTECTIVE MEASURES AGAINST AIR-BURST BOMBS

In an attack against an unwarned British city, then the casualties would number tens of thousands, and among the survivors there would be very many thousand burns, many thousand wounds, and probably several thousand cases of radiation sickness. Since there might well be many atomic bomb attacks, the prospects of a future war are appalling. Action can be taken to reduce the human suffering from each attack, but it must not be forgotten that future attacks would probably be made with more powerful weapons than those seen in Japan. The defensive measures will now be discussed in order of their probable sparing action.

(1) Warning and Shelters

If warning of air-raids could be given, and the population outdoors could take cover in suitable shelters, casualties would be mainly restricted to the zone of blast, a radius of up to 3000 yards. In other words, it is likely that the area from which survivors would emerge could be divided by at least 2 and by up to 16 in the most favourable circumstances, if all were protected. But an atomic bomb attack might be made during an air raid with the result that civilian defence workers on duty in the open would be injured even in the outer zones. There would thus be a serious risk of losing vital personnel. Some protective action could be taken to shield all these people, as described below.

(2) Individual Evasion and Protection

The provision of protective clothing against gamma radiation seems impossible. It would have to be as heavy as thick concrete. Against this may be set the relatively slow emission of gamma radiation after the first second and therefore the possibility of evasion. A crouching posture facing away from the flash is suggested by the American writers, for this might reduce the total angle subtended at the source of the bomb. However they do not say whether gamma radiation is largely reflected by the earth and buildings. If it is, this might invalidate the evasion of gamma radiation by this posture.

Some protection against blast might be given by thick clothing to prevent penetration by glass. Further

1. The first of these is the fact that the Japanese government has been unable to secure the necessary international cooperation for the implementation of its policy. This is due to the fact that the Japanese government has been unable to secure the necessary international cooperation for the implementation of its policy.

Reconstruction

THE QUALITY OF MEDICAL CARE

An American Report

FROM A CORRESPONDENT

THERE are two ways of starting a national health service. The first is to set an appointed day and drive on regardless of difficulties. The second is to examine the subject from every conceivable angle and try to define the detailed pattern in advance. Both have their drawbacks. The first method may mean improvisation, and retaining practices of doubtful value. Costs may prove to be unexpectedly high, and some group or other is bound to be dissatisfied. Above all, extensive remodelling of the scheme in the light of experience is almost impossible. With the second method much time may be wasted in theoretical discussion, and, at the worst, the service never gets launched at all, but, given good will, the difference between the first project and the final one may be as great as the difference between a racing yacht and a converted trawler. The ideal would, of course, be to combine the best of both methods and, from carefully prepared blue prints, to undertake limited trials with full operation to come later in orderly sequence.

The Americans are entering the blue print stage, and a stream of reports by experts is appearing. One of these, produced for the American Public Health Association by a committee headed by Dr Dean A. Clark, is of unusual interest.¹

ESSENTIALS

It begins by saying that a national health programme must assure full freedom of experiment and change in both the science and organisation of health services. It recognises that most measures for the promotion of health are social or educational, and that medical care must be planned with the whole picture in mind.

The standards laid down for medical care are quantitative and qualitative. The former are those with which we are already familiar but include also the education of the public as to the best use of the services. The requirements as to quality are

- 1 Able well trained, and efficiently functioning personnel
- 2 Facilities and equipment which meet high technical standards
- 3 Health services which encompass the best knowledge of modern medical science, and which ensure availability and continuity of care
- 4 Adequate financial arrangements, making possible the timely provision of all indicated services without economic deterrents for patients or practitioners
- 5 Sound administrative organisation and operation designed to promote efficiency and economy of service

The first component of good quality to be discussed is the selection and education of doctors, and emphasis is laid on the need for pre professional education in the humanities and social sciences. The need to keep the medical curriculum constantly under review is emphasised, and the comment is made that no medical student should be graduated without study of the psychological, social, economic, occupational, and other aspects of "total" patient care. This is to be achieved by active participation of the medical school in organised community programmes of health and medical care and by ensuring that all graduates are experienced in outpatient service, home care, social service, public health practice, rehabilitation, and work in rural and small community hospitals. Postgraduate education should, it is said, include visits by consultants and teachers travelling out

¹ The Quality of Medical Care in a National Health Program, a statement by the Subcommittee on Medical Care, American Public Health Association. Reprinted from *Amer J publ Hlth* 1949 39 898

from the teaching centre to local meetings, clinics, and ward rounds. The unusual suggestion is made that qualifications of licensed practitioners might be reviewed periodically so as to safeguard the quality of care provided.

GENERAL PRACTICE

Practitioners here in England will agree that the greatest single deterrent to good service is the isolation of the individual practitioner from his colleagues, and that doctors should be free from the burden of non professional chores, with enough time and incentive to read, attend lectures, and otherwise improve their knowledge and skill. Another point of particular importance in the light of the controversy centring round the Collings report is that the general practitioner, if given complete consultant reports, "can usually continue with the management of all but the most specialised therapeutic procedures." Efforts to enhance the prestige of the general practitioner in the United States have included the establishment of general practice sections in hospitals and medical societies. A "specialty board" in general practice is under discussion. The report tilts at the inefficiencies of unsupervised medical "shopping."

Stress is laid on group practice as the mainstay of quality, but the authors of this report mean far more by this term than we do. They are thinking of a community health and medical centre supplying the fully coordinated and balanced health service needed by a local population. This involves not only joint housing of hospitals and health departments but the establishment of offices for private practitioners and medical groups within the hospital. In 1948 the A.P.H.A. and the American Hospital Association issued a joint statement emphasising the advantages of hospitals and health departments working together. This need to integrate preventive and clinical medicine by the use of buildings in common, by making hospital and health areas coterminous, and by functional links with group and rural practitioners, pervades the whole of the present report. Thus the definition of "prevention" is extended to include the prevention of continuance or progress of a disease which has already begun. "In other words, effective preventive services requires prompt, comprehensive, and continued personal care as well as community service of the kind traditionally associated with public health activity."

ADMINISTRATION

On economic and administrative control the report is uncertain and sometimes almost contradictory. This is implicit in any report which sets out to describe the ideal and has at the same time to admit that some limitations will be necessary, at least initially, until the medical and administrative resources of the nation are better developed and organised. The administrative safeguards of procedure manuals (even if liberally interpreted and frequently reviewed), statistical audits, and prior administrative authorisation for selected services have an ominous ring. On the other hand, everyone will agree that rates of payment should be flexible, adequate, and proportionately related to skill, experience, and responsibility, and that they should be determined in advance by competent experts in the particular field. Capitation or salary payment is preferred to fee for service—provided group medical practice is adopted. "In a group, the compensation of each physician depends not only upon his own efforts, but also upon the success of the group as a whole, and the judgment of his fellows regarding his contribution to the group's success. The reputation of the entire group is at stake in the satisfaction of patients with the services of all physicians in the group."

On the subject of hospital administration the authors are on sure ground when they say that those in charge

people outside the central zone would have two or more seconds' warning of the approach of the blast wave (it should be borne in mind that they have not yet heard the noise of the explosion but would only have seen the flash). They might well be able to adopt a suitable posture if out in the open, or gain some sort of cover from glass and falling masonry in doorways if they were in a city street.

Once the bomb has exploded, the chances of greatly reducing the dose of radiant heat are low. Extremely swift action would be needed to avoid flash burns. Protection against the radiant heat would mainly consist in also covering the exposed parts of the body. The hands and faces in men, and the legs also in women and children, could be protected by gloves, wide brimmed hats, and trousers for the female and child population. This simple "protective" clothing, especially for the hands and face, would also reduce the number of secondary burns, for in escaping from a house or street the exposed skin would be subject to a greater risk of burning than skin covered with thick non-inflammable clothing. In this way the number of minor burns could be greatly reduced—as regards the serious burns from inflammable clothing, common sense dictates that the wearing of such fabrics in war, when incendiary or atomic attacks might be made, would be the utmost folly. The population should be warned strongly of the extra risk of flimsy combustible materials. By not wearing such fabrics the number of major burns could be reduced. The ideal protective uniform for those whose duties exposed them to a high risk of burning would be non-inflammable, and of high reflectivity, though being light in colour or having a metallised surface, and would be a very poor conductor of heat. It should cover as much of the body as possible.

These measures might well reduce the casualties of Japan. If atomic bombs become more powerful, such preventive measures will be even more necessary.

Planned Care for Casualties

Despite all actions, warnings, shelters, evasion, and protective garments, and even the common sense measures described above against burns, it is impossible to release the energies of an atomic weapon over a city and not inflict thousands of casualties. The fundamental problem of medical treatment would be to prevent economic loss from long convalescence from unhealed burns, septic lacerations, ununited fractures, and gamma radiation. The task would be unique in two important aspects: the large number of civilian casualties and the suddenness thereof. At every turn the planner of medical defence against an atomic weapon finds himself confronted with the sudden appearance of very large numbers of very many sorts of casualties. Unless the doctors knew what types of injury to expect, and unless there were some sort of scheme behind the medical activities after an explosion, chaos of the scale seen in Japan would certainly ensue.

UNDERWATER AND UNDERGROUND ATOMIC EXPLOSIONS

It is much more difficult to predict the results of underwater and underground atomic explosions than of those in the air. From the medical point of view such explosions would produce immediate casualties from blast, and delayed casualties from radiation.

Underground Explosion

In the case of a shallow (50 ft) underground atomic explosion the areas affected by blast would be between a quarter and half the size of the areas for corresponding

damage by blast from an air burst atomic bomb. Thus the blast casualties would be far fewer. Further, there would be fewer flash burns. However, gamma radiation sickness might be more widespread; for, although the immediate radiation emitted from the bomb would be blocked by the ground, there would be a large amount of radioactive dust which would fall near the crater. No estimates are given for its limits of dissemination. This radioactive dust would be a biological hazard where it fell, for the radiations emitted during radioactive decay might not only fall as external radiation directly on to people but also enter the body by inhalation or by ingestion in contaminated water and so produce internal radiation. Internal radiation casualties would be comparable to radium poisoning. These serious risks could be greatly reduced by competent monitoring for dangerous radiactions, and by suitable washing and chemical decontamination, all of which processes are primarily civilian defence responsibilities. The American book gives a good deal of information about apparatus and methods for these procedures.

Underwater Explosion

Rather more information is given in the book about underwater explosions, based on the Bikini underwater test. From the medical point of view blast casualties would come from areas just over a quarter of the size of those for comparable damage from an air burst bomb. With a wind blowing at 5 m.p.h., radioactive water droplets could be a lethal hazard to exposed human beings over an area of 10 sq miles. However, as with underground explosions, there would be no flash burns, far fewer (roughly a quarter) secondary burns, and far fewer blast casualties (again roughly a quarter), compared with an air burst atomic bomb. Because of the difficulties of prediction with these two types of atomic weapons, and the vagaries of the British climate, it seems prudent to postpone any attempt to assess the medical problems involved until we have more information. Some evasion might be achieved by taking shelter in the interval of several minutes between the explosion and the settling of the dust or water droplets, and by wearing respirators and by suitable monitoring thereafter. However, decontamination and the subsequent rescue of those sheltering would certainly be a very difficult operation, requiring heavily protected vehicles (tanks) and excellent civilian morale and discipline.

CONCLUSIONS

A great deal can and is being done to shield the population from injury in this terrible form of warfare. But even so, there would be many casualties, especially if there were multiple attacks with more efficient bombs. The first aid posts would be overwhelmed at first with abundant minor casualties from the fringe of the attack, and these people might well interfere with the handling of more serious cases arriving later. Amid all this turmoil there would be serious problems of morale and other difficulties, including feeding and housing refugees, working without main services, and training missing persons, down to the keeping of proper medical records and no os and articles on this subject in an optimistic vein, calling for organisation to meet the peril and for general preparedness. No attempt has been made here to assess the medical burden of atomic warfare in terms of hospital beds, miles of bandages, bottles of plasma, and the number of doctors required. Those interested in such statistics can make their own computations from the data given. Those who do so will find it difficult to remain optimistic when their calculations are finished.

For the next three weeks I went back to the lab once a week, my wife going with me, but though we took the bus, I gradually found myself feeling weaker, and my pallor was returning. Nor could I manage to do anything at home; I usually had my breakfast in bed and managed to get up for my dinner, but then I only sat about in the garden or indoors. I noticed that the lack of blood even seemed to affect my brain, I was slower to grasp anything, and I could not concentrate enough to read. We occasionally enjoyed a game of cards with our friends, but even at this I used to feel myself getting easily excited, whereas before my illness nothing ever ruffled me. By the end of the third week at home I was feeling pretty low again, and the doctors asked me to go back into hospital on the following Monday. I had a bad day on the Sunday—in fact I was so weak I almost fainted over my dinner, and had to get to the window for air. I felt stifled as though I could not breathe, and could hardly drag myself upstairs. I had to do the trip down to the city on the Monday in a taxi.

I had a transfusion of three pints of concentrated cells on the Tuesday and again on the Thursday, by which time I looked like a farmer's boy (so my visitors told me) and felt uncomfortably full. I was allowed home again after a week, and the doctor decided to keep my blood count up to a decent level by giving me weekly transfusions in the lab. Friday was now set aside in my life as transfusion day, and it was the only day of the week when I now set my alarm clock, for work was still out of the question. I used to go up by bus, taking coffee and sandwiches with me. A heavy meal on this day was more than I could manage, though I always enjoyed my meal when I got home. This was usually wholesome but light—perhaps steamed fish, or something like that. I arrived at the lab about 11 o'clock, had my blood count done, and was settled on the "drip" by about 12.30. After taking about a quarter of the blood, I could feel a marvellous sense of smoothness surging over me, my head stopped buzzing, my heart quietened down, and above all the pressure seemed to lift from my eyes—they seemed to open wider. I could then settle down to a quiet smoke, and perhaps read the magazine or book I had brought with me. I had my lunch about 1.30, and got used to managing with one hand only, as the other was being used for the transfusion. My average "drip" was 32 to the minute, I know—I often counted them.

My wife could join me after lunch. I usually finished about 5 o'clock, and then we went home by bus. I think I was pretty fortunate in not having many rigors or reactions to the transfusions, though there were odd times when things were not so good. One day, on getting off the bus, I suddenly developed nettlerash, but this was short-lived once the doctor had given me an injection. It would be untrue to say I never had a rigor, I have known what it is to feel very bad pains in my legs, groins, and back, and find myself shivering and shaking all over with a temperature of 101°F. On such occasions I used to sit by the fire in the lab and take things easy until I had got back to normal, before going for my bus. After my evening meal I used to go straight to bed with a hot water bottle, and sleep until lunch time next day.

This went on for two years, during which I was always looking forward to a time when the period between transfusions could be lengthened. This never seemed to come, and sometimes the future seemed hopeless. I think the first twelve months were the most trying, because I could not concentrate and everything was a trouble. But I rather looked forward to my weekly visit to hospital, for otherwise I could not get about much, and I knew the doctors were doing their utmost. In the second year I seemed to regain some of my former

energy and concentration, and was able to knock about a little more, pottering about the garden, and even playing bowls in the park and visiting the open air baths. I did not feel any after effects from these strenuous pastimes, and I could even take short rides on my bicycle. I had gradually become used to the changed ways which my illness had thrust upon me, and was determined that if I was not for this world for long, at least I would enjoy myself in a quiet way with my wife and friends for as long as possible. We managed to be content and keep cheerful, and even spent a day at Old Trafford watching England and the Australians, including the famous Don Bradman. But it was a typical wet Manchester "Test" day, and I caught a bad cold, which developed into bronchitis. By the next transfusion day my blood count had fallen more than usual. I had to go down to the hospital for an extra pint on a second day that week. Through it all my wife helped me tremendously, she never complained and was always cheerful.

The amazing thing is that my recovery was not gradual, as I had always expected, but just as sudden as my illness. One night, at the end of March, 1949, I had very bad pains in my groins and upper portions of my legs. They often used to come on at bed time, but this time, though my wife massaged me and gave me a hot water bottle, the pain became so acute I simply had to get out of bed and walk about to try and get a little relief. After about an hour or so, it subsided, leaving me perspiring and weak. It seemed to me very similar to a reaction after a transfusion, though I had had no reaction at the time of the transfusion that week. For about a month I really suffered, so much so that I began to think I was at last breaking up. Then, as suddenly, these attacks ceased, and never occurred again, and the curious thing is that I started producing my own blood from about then.

On May 27, 1949, my hæmoglobin had bumped up in a week from around the 70s to 96%, and the thing I had so long been hoping for happened at last—I actually missed a transfusion. My wife would not believe me, she thought I was joking, and we didn't dare to mention it to anyone in case it was a fluke. I still had to go down prepared for a transfusion each Friday, and could not believe my ears when each time the news was good. So it went on through the summer, and what a glorious summer it was—not only because of the weather, though even this excelled itself, but because after 83 transfusions I had at long last begun to make my own blood again.

I have thanked God for the people in this troubled world today who give so freely of their blood, but all the same I felt a free man when I was no longer depending on them for life. We went away for a few weeks to the seaside, where I swam and knocked about as in the times before my illness. I never felt tired or languid, in fact I had untold energy, and on my return in September the doctors advised me to try a spot of work, as I was in such rude health.

Now came my reablement at my old job. I had to go before the Railway Company's doctor, who told me what a lucky man I was—as if I didn't know!—and so I began working for a living again. Those early turns, which mean rising at 5 o'clock in the morning, those night duties and late turns. Still, I shall never grumble again, I am too thankful to be able to work at all. I have now been back at work for six months, and it is surprising to find how quickly and easily I have slipped back into line. I feel and look very fit, and never cease to marvel at my wonderful recovery. To any fellow sufferer my advice is: keep your chin up, put your faith in the doctors' skill, and—to use my favourite expression—relax.

Disabilities

52 APLASTIC ANEMIA

IT was in June, 1947, that I was stricken with aplastic anaemia. Before then I had always had good health and had not needed any time off work at all for six weeks during 21 years on the railway. I am a relief signman, special class, which entails working at the largest boxes, the work is heavy and responsible, so it was rather surprising that, though I was beginning to look pretty shabby even at the start of my illness, I could still cycle to work and manage my shifts without exhaustion.

My wife had been urging me to see a doctor, because she had noticed that I was losing my colour in lips, gums, and ears, in fact she said I looked as pale as a corpse. I kept answering, "I'm all right—it's only my early turn" (which meant getting up at 5 A.M. each morning), "I'm probably tired." "Anyhow," on the second Sunday in June we were going to see some friends. We had a short walk uphill to their house, and half way up I realised there was something really wrong, for my legs just stopped and refused to move, my heart was pounding in my chest, and I could hardly breathe. I was carrying a machine over my arm at the time, and my wife had to take it off me—it felt like a ton weight. After a rest we continued to the top of the hill, and there and then I agreed to go to the doctor on the Monday, and so I did. He said I must see a specialist immediately—the himself could do nothing for me, and could not say what was the matter. When I saw the specialist he wanted me to go into the wards for observation. I did not relish the idea, but in time I went.

It was the first time I had been in hospital as a patient, and after the first few days I was confined to bed, which made me realise how ill I was. After about 10 days I was given my first transfusion. Since I had read that these were only given in emergencies, and since I had already failed to respond to liver injections, I thought I must be in a sorry plight. I went through all manner of examinations, and though I didn't like them I was able to take them as a matter of course, for I know well enough that if a machine breaks down it is necessary to examine the workings to find the fault. One day I was sent by ambulance to see a doctor at a hospital which has a special department for blood diseases. This seemed to show I was suffering from a very obscure disease, and accordingly I felt rather pleased that I was getting someone important to delve further into things. When you've been lying in bed for three weeks such small things as this seem to relieve the monotony, and I quite enjoyed my day out with my wife, even if it was only a trip from one hospital to another in an ambulance and this was the first time I had seen the inside of a lab. The doctor there wanted me transferred to his care, and a week later my wife escorted me there. I once more had to undergo many tests and X-ray examinations, but I was in good hands, and the quiet efficiency of the department of haematology inspired me with new hope.

My first blood transfusion had not been a very pleasant experience, but after about half a dozen I began to take them as a matter of course, my biggest worry being my apparent lack of veins. One day, one of the doctors said he would like to try a marrow from showing that my marrow was only dormant, and not dead, but I shall always be grateful to the doctor. After about six weeks, when they had built my strength up with blood transfusions, I was allowed to go home.

of administration should be experts in this field, specially trained, properly paid, and chosen on a merit system. The use of expert consultants is advised, and by hospital consultant is meant a man in active practice and not one who has made an armchair study of the subject. Methods of payment to hospitals are discussed in detail, and the best approach is thought to be to pay hospitals on a cost basis with different ceilings for hospitals providing services of differing scope and standards. The authors emphasise that no system of paying hospitals is workable in the absence of good cost accounting on a uniform basis. Incentives to encourage doctors to settle in rural areas should include specially provided equipment and facilities, loans or grants for expenses while the new practice is being set up, assurance of a sufficient income, and functional affiliation with urban resources.

After reviewing the circumstances which underlie the existence of chiropractors, faith healers, naturopaths, and the like, the report recommends the elimination of untrained practitioners from participation in payment under the programme, and the elevation of educational standards of those groups not close to the concept of scientific medicine, "as are certain groups of osteopaths," though the medical assistance to be approved schools. This could make possible eventual incorporation of such personnel and their teaching institutions and hospitals into the regular ranks of medical personnel serving the public.

On hospitalising the report remarks that good medical care is impossible to provide in isolation and that it seems desirable to reverse the accustomed "closed staff" arrangements and to allow all licensed practitioners to utilise the hospital provided that they are restricted to activities within their scope and supervised and aided in their work by the whole professional staff of the institution. The words "self appraisal" come more naturally to American than British lips, but the sincerity of their use is unquestionable, and we might with benefit study the system of medical audit which has been used for many years by a few leading hospitals in the United States and is now said to be coming into more general favour. This is a periodic audit by the entire medical staff of the work performed in the hospital. On the basis of comprehensive and uniform record keeping, analyses are compiled which show the morbidity and mortality experience of each service and each individual staff member over a period. Initial diagnosis and prognosis are compared with the results of hospital treatment, and the results become the basis for self-education and improvement, for the discovery of new procedures, and for the discovery of sources of poor work in the institution. Everyone will agree with the authors of this report that the quality of medical care neither deteriorates nor improves automatically with the mere establishment of a national programme, and that in the modern technological age the tendency to lose sight of the individual patient is very strong. No service can afford to neglect quality in favour of quantity.

THE MEDICAL AUDIT

For many years the physician rigidly restricted the fluid intake of edematous persons, with no voice, but the patients raised in protest Surgical and obstetric patients were likewise kept at prolonged postoperative or postpartum bed rest until critical thought and perhaps the shortage of beds, stimulated the re-examination of the evidence. There is no statistical evidence that bed rest, or even markedly restricted activity over a prolonged period, advantageously affects either the course or the later sequelae of myocardial infarction. No controlled series of cases has been reported. Yet bed rest has long been the *sine qua non* in the treatment of myocardial infarction—Dr C. W. Alexander, Irvine, Jun., and Dr Alexander M. Burgess, Jun. *New Engl. J. Med.* 1950 243, 486

Parliament

Dangerous Drugs (Amendment) Bill

IN the House of Commons on Nov 9, this Bill was introduced and read a first time. It removes limitations on the extension to Northern Ireland of Acts amending the Dangerous Drugs Act, 1920. It also makes other amendments of law made necessary by the supersession of the League of Nations by the United Nations.

QUESTION TIME

Kingston Victoria Hospital

Mr J A BOYD CARPENTER asked the Minister of Health what decision he had taken as to the future of this hospital and what steps he was taking to ensure that facilities for treatment of the patients in the hospital would continue to be available to general medical practitioners in this district.—Mr ANEURIN BEVAN replied. This hospital is to be used as a gynaecological unit. The Surbiton annexe hospital is to be converted to give alternative facilities to general practitioners.

Mr BOYD CARPENTER. When is the Surbiton annexe to be converted and what is to happen to the patients during the interval before the conversion is completed?—Mr BEVAN. Arrangements are being made for the other patients, and the Surbiton annexe will be furnished and refurbished as soon as we are aware that the general practitioners are prepared to make use of it. Mr BOYD CARPENTER. Is the Minister aware that there are at the moment 37 patients in this hospital who are seriously ill, that the regional board is making every effort to close it and that no alternative exists at present?—Mr BEVAN. The hon. member must take it for granted that whenever a hospital is changed from one specialty to another arrangements are invariably made for the care of the patients. Mr BOYD CARPENTER gave notice that he would raise the matter again at the earliest opportunity.

Advertised to the Public

Mr GEORGE JEGGER asked the Minister, in view of the difficulties of National Health Service doctors in resisting the demands of patients for prescriptions for medicinal preparations advertised direct to the public, what steps he proposed to take to deal with this matter.—Mr BEVAN replied. Responsibility for prescribing should rest solely on the judgment of the doctor. Sir Henry Cohen's committee on prescribing therefore recommended that publicly advertised preparations should not be prescribed under the National Health Service. This recommendation has been sent to all doctors, who have been asked to observe it, and any doctor who refuses importunate demands has my full support.

Mr JEGGER. Is the Minister aware that there is a section of the medical profession that has been organised to collect funds to resist the health service, and would he appeal to them to divert these funds towards the education of the medical profession in the direction which he has just outlined?—Mr BEVAN. From the preliminary information at our disposal, I believe that the recommendation of Sir Henry Cohen's committee is being carried out generally. I would not like to believe that the doctors require any further education, but if they do require it we shall, of course, consider what we have to do.

Mrs JEAN MANN. Is the Minister aware that many doctors are greatly perturbed at the wide latitude allowed to them for over-prescribing and that many are protesting and asking that the old procedure, whereby prescriptions were properly scrutinised, should be reintroduced?—Mr BEVAN. Yes, I believe that is so, but that is a different question.

Hearing-aids Bone-conduction Types

Mr A J CHAMPION asked the Minister of Health if he would extend the provision of hearing aids to include bone conduction types.—Mr BEVAN replied. Yes, but I can do so only after the necessary technical investigations are complete and as soon thereafter as production can be organised.

Priority Food Rations for Tuberculous Patients

Miss M P HORSBY SMITH asked the Minister of Food what priority food rations were granted to people suffering from tuberculosis, and what alterations in such priorities had been made this year.—Mr MAURICE WEBB replied. Three eggs a week, and a double ration of butter or margarine which at present gives an extra 4 oz. Before June this year

the weekly allowances were three eggs, an extra 3 oz of butter or margarine and an extra ounce each of cooking fat and bacon. When milk was controlled the priority supply was 14 pints a week.

Transferred Patients

In answer to an inquiry why the names of 5 people, all of whom had been his patients for over twenty years, had been removed from the list of Dr A Green, 385, Erith Road, Erith, Mr BEVAN replied that Dr Green had a list of 520 patients, the normal agreed maximum being 4000. As Dr Green would do nothing to help the executive council to meet this situation, they had to take whatever steps seemed best to them. On the whole, Mr Bevan thought, they had acted reasonably, in difficult circumstances.

Pay of Medical Personnel in the Services

Replying to a question by Wing Commander N J OULHELI, who asked the Minister of Defence if he would make a statement in regard to the pay increases for the medical branch of the Services, Mr EMANUEL SHINWELL said this matter had been very complicated but he hoped to make an announcement shortly.

Corporal Punishment for Crimes of Violence

Replying to questions, Mr CHUTER EDE Home Secretary said he was satisfied that the penalties prescribed by law for crimes of violence were adequate. The Government had no intention of reintroducing corporal punishment, which after full discussion was abolished as a judicial penalty by section 2 of the Criminal Justice Act, 1948. That Act marked a notable advance in the treatment of offenders, and it would be premature to consider further changes in the law until more experience had been gained by its working. The current thing was that the offences not previously punishable by flogging had increased 25.76%, while those punishable by flogging had increased by only 1.93% since the repeal of the power to flog.

Currency for Tuberculosis Treatment Abroad

Mr D T LLEWELLYN asked the Chancellor of the Exchequer how many applications had been made to the Medical Advice Board for the release of currency, in excess of the normal limit allowed, by applicants wishing to go to tuberculosis sanatoria abroad for each of the years since the Board was established, and how many applications were granted.—Mr HUGH GAITSKELL replied. The Exchange Control Medical Advisory Committee was set up in December, 1947. No figures are available for the period from the formation of the committee until the end of February, 1948. The figures for subsequent periods are

	No of applications received	No of applications granted
March 1 1948 to Feb 28 1949	1238	1135
March 1 1949 to Feb 28 1950	1062	986
March 1 1950 to Aug 31 1950	287	283

These figures include renewal applications from people already granted currency who wish to prolong their treatment abroad.

Public Health

Poliomyelitis

IN England and Wales notifications of poliomyelitis during the week ended Nov 4 were paralytic 147 (182), non-paralytic 57 (71), total 204 (253). The figures for the previous week are in parentheses. Notification for the corresponding week in 1947 and 1949 totalled 243 and 330.

Total uncorrected notifications for 1950 to and including the week under review are 7747. The corresponding figures for 1947, 1948, and 1949 are 8205, 2050, and 5589.

Estimate of Future Births

The Registrar General's final estimate¹ for births in England and Wales during the December quarter of this year is 100,000, and the provisional estimate for the March quarter, 1951, is 170,000, giving an estimated total of 330,000 in the six months. There were 109,302 live births in the December quarter of last year, and 180,062 in the March quarter, 1950—a total of 349,364.

Parliament

Dangerous Drugs (Amendment) Bill

IN the House of Commons on Nov 9, this Bill was introduced and read a first time. It removes limitations on the extension to Northern Ireland of Acts amending the Dangerous Drugs Act, 1920. It also makes other amendments of law made necessary by the supersession of the League of Nations by the United Nations.

QUESTION TIME

Kingston Victoria Hospital

Mr J A BOYD CARPENTER asked the Minister of Health what decision he had taken as to the future of this hospital and what steps he was taking to ensure that facilities for treatment of the patients in the hospital would continue to be available to general medical practitioners in this district.

—Mr ANEURIN BEVAN replied. This hospital is to be used as a gynaecological unit. The Surbiton annexe hospital is to be converted to give alternative facilities to general practitioners.

Mr BOYD CARPENTER. When is the Surbiton annexe to be converted and what is to happen to the patients during the interval before the conversion is completed?—Mr BEVAN. Arrangements are being made for the other patients, and the Surbiton annexe will be furnished and refurbished as soon as we are aware that the general practitioners are prepared to make use of it. Mr BOYD CARPENTER. Is the Minister aware that there are at the moment 37 patients in this hospital who are seriously ill, that the regional board is making every effort to close it and that no alternative exists at present?—Mr BEVAN. The hon. member must take it for granted that whenever a hospital is changed from one specialty to another arrangements are invariably made for the care of the patients. Mr BOYD CARPENTER gave notice that he would raise the matter again at the earliest opportunity.

Advertised to the Public

Mr GEORGE JEGEER asked the Minister, in view of the difficulties of National Health Service doctors in resisting the demands of patients for prescriptions for medicinal preparations advertised direct to the public, what steps he proposed to take to deal with this matter.—Mr BEVAN replied. Responsibility for prescribing should rest solely on the judgment of the doctor. Sir Henry Cohen's committee on prescribing therefore recommended that publicly advertised preparations should not be prescribed under the National Health Service. This recommendation has been sent to all doctors, who have been asked to observe it and any doctor who refuses importunate demands has my full support.

Mr JEGEER. Is the Minister aware that there is a section of the medical profession that has been organised to collect funds to resist the health service, and would he appeal to them to divert these funds towards the education of the medical profession in the direction which he has just outlined?

—Mr BEVAN. From the preliminary information at our disposal, I believe that the recommendation of Sir Henry Cohen's committee is being carried out generally. I would not like to believe that the doctors require any further education but if they do require it we shall, of course, consider what we have to do.

Mrs JEAN MANN. Is the Minister aware that many doctors are greatly perturbed at the wide latitude allowed to them for over prescribing and that many are protesting and asking that the old procedure, whereby prescriptions were properly scrutinised, should be reintroduced?—Mr BEVAN. Yes, I believe that is so, but that is a different question.

Hearing-aids Bone-conduction Types

Mr A J CHAMPION asked the Minister of Health if he would extend the provision of hearing aids to include bone conduction types.—Mr BEVAN replied. Yes, but I can do so only after the necessary technical investigations are complete and as soon thereafter as production can be organised.

Priority Food Rations for Tuberculous Patients

Miss M P HORSBY SMITH asked the Minister of Food what priority food rations were granted to people suffering from tuberculosis, and what alterations in such priorities had been made this year.—Mr MATRICE WEBB replied. Three eggs a week, and a double ration of butter or margarine which at present gives an extra 4 oz. Before June this year

the weekly allowances were three eggs, an extra 3 oz. of butter or margarine and an extra ounce each of cooking fat and bacon. When milk was controlled the priority supply was 14 pints a week.

Transferred Patients

In answer to an inquiry why the names of 5 people, all of whom had been his patients for over twenty years had been removed from the list of Dr A Green, 385, Erith Rd, Erith, Mr BEVAN replied that Dr Green had a list of 57 patients, the normal agreed maximum being 4000. Dr Green would do nothing to help the executive council to meet this situation, they had to take whatever steps seemed best to them. On the whole, Mr Bevan thought, they had acted reasonably, in difficult circumstances.

Pay of Medical Personnel in the Services

Replying to a question by Wing Commander N J HURST who asked the Minister of Defence if he would make a statement in regard to the pay increases for the medical staff of the Services, Mr EMANUEL SHIRWELL said this matter has been very complicated but he hoped to make an announcement shortly.

Corporal Punishment for Crimes of Violence

Replying to questions, Mr CHUTEER EDE, Home Sec., said he was satisfied that the penalties prescribed by law for crimes of violence were adequate. The Government had no intention of reintroducing corporal punishment, and after full discussion was abolished as a judicial penalty in section 2 of the Criminal Justice Act, 1948. That Act marked a notable advance in the treatment of offenders, and it would be premature to consider further changes in the law until more experience had been gained by its working. The current thing was that the offences not previously punishable by flogging had increased 25.76%, while those punishable by flogging had increased by only 1.93% since the repeal of the power to flog.

Currency for Tuberculosis Treatment Abroad

Mr D T LLEWELLYN asked the Chancellor of the Exchequer how many applications had been made to the Medical Advice Board for the release of currency, in excess of the normal limit allowed, by applicants wishing to go to tuberculosis sanatoria abroad for each of the years since the Board was established and how many applications were granted.—Mr HUGH GAITSKELL replied. The Exchange Control Medical Advisory Committee was set up in December, 1947. No figures are available for the period from the formation of the committee until the end of February, 1948. The figures for subsequent periods are

	No of applications received	No of applications granted
March 1 1948 to Feb 28 1949	1224	1135
March 1 1949 to Feb 28 1950	1062	936
March 1 1950 to Aug 31 1950	287	283

These figures include renewal applications from people already granted currency who wish to prolong their treatment abroad.

Public Health

Poliomyelitis

IN England and Wales notifications of poliomyelitis during the week ended Nov 4 were paralytic 147 (182), non-paralytic 57 (71), total 204 (253). The figures for the previous week are in parentheses. Notifications for the corresponding week in 1947 and 1949 totalled 243 and 330.

Total uncorrected notifications for 1950 to and including the week under review are 7747. The corresponding figures for 1947, 1948, and 1949 are 8265, 2050, and 5589.

Estimate of Future Births

The Registrar General's final estimate¹ for births in England and Wales during the December quarter of this year is 100,000, and the provisional estimate for the March quarter, 1951, is 170,000, giving an estimated total of 330,000 in the six months. There were 169,302 live births in the December quarter of last year, and 180,062 in the March quarter, 1950—a total of 349,364.

Letters to the Editor

REGISTRARS

SIR,—Mr Bevan's solution of the excess-registrar problem will rate him with George Washington as an axe-wielder. Having spent sixteen years since leaving school growing big enough to be worth chopping down, I can provide a better solution. It is simply to make eight hundred senior registrars into consultants without more ado. Thus, at one blow, will restore a favourable balance and relieve the alleged shortage of consultants both in the Services and the National Health Service. It will also have the merit of pleasing the registrars, which cannot be said for Mr Bevan's plan. It may not, of course, please the present consultants.

Royal Infirmary
Bradford

J C ANGELL
Senior Surgical Registrar

SIR,—There is a difficulty in arriving at a satisfactory registrar establishment which is only touched on in your last issue but is more fully discussed in the *Times* of Nov. 10. This is that the number of consultant posts available is very small, while many hospitals urgently require a larger number of senior registrars to get the work done.

There is a very simple solution for this problem which nobody seems to mention. It is to prolong the period of tenure of the senior posts. If these were tenable for a total of six years, for instance, hospitals could employ double the number of registrars for the same number of trained men produced, since the frequency of vacancies for registrars would be reduced by half.

With present salaries this would be no hardship to the registrars, and can one maintain seriously that a senior registrar after three years is a fully trained consultant at, possibly, the age of 29?

SENIOR REGISTRAR

NUTRITION AND ANTIBODIES

SIR,—In your leading article of Oct. 28 you say that "the importance of the lymphocyte in antibody production is now well established," and refer to three reports.

McMaster and Hudack¹ and Oakley et al.² made fundamentally the same experimental approach—i.e., estimation of antibody ratios within regional and contralateral lymph glands after antigen injections. No histological descriptions are given and the particular cell responsible for antibody production remains a matter for conjecture. Ehrlich and Harris³ carried out antibody extraction studies on rabbits, using the popliteal gland after subcutaneous injection of antigen into the feet, and these experiments warrant the conclusion that under these conditions antibody was being manufactured or stored in this lymph gland. These workers examined histologically the lymphoid tissues involved, and they also examined the cells within the efferent lymph during the period of antibody production. They concluded "The fact that the tissue response accompanying the formation of antibodies was chiefly a lymphocytic one, points to the lymphocyte as a factor in the formation of antibodies." However, Ehrlich et al.⁴ later came to a quite different conclusion; they found from a study of the lymphoid tissues during the initial period of antibody production, that the cellular response was chiefly one of plasma cells. Furthermore "The present study of sections through efferent lymph vessels suggests that some of the lymphoid cells that leave the lymph node during the period of antibody production are plasmoblasts and plasma cells." And

"these results are interpreted as indicating that the plasma cell and not the lymphocyte is responsible for antibody production."

In view of these facts, the interpretation of the results of Stoerk et al.⁵ (impairment of antibody response in the pyridoxine deficient rat) in terms of the cytology of the lymphoid tissues, must await clearer elucidation of the status of the lymphocyte as an antibody-producing cell.

THE KEMPNER RICE DIET

SIR,—It is clear from your leading article last week that one of the principal drawbacks of the rice diet is its unpalatability. Dr Bircher Benner of Zürich, has for many years been administering a vegetarian, low salt diet to his patients, and claims good results in hypertension. The great virtue of the Bircher Benner diets is that they are extremely palatable, and so there is no difficulty in persuading patients to take them indefinitely. It seems a pity that the work of this Swiss pioneer was not investigated long ago with the same care as has now been devoted to assessing the Kempner régime.

COURSES FOR SENIOR NURSES

SIR,—We feel that members of the medical profession would like to be told of an undertaking very near our hearts. The education department of the Royal College of Nursing provides post certificate courses to equip nurses for administrative and teaching posts as tutors, as industrial nurses, and in the field of public health. The college has always been the pioneer in this work, today the high quality of its advanced courses and its modern approach are universally acknowledged, and the courses are attended by hundreds of students not only from the British Isles but from the Commonwealth and other countries overseas.

No educational body expects to recover its costs from students' fees alone, and these and the grant received from the Ministry of Education are quite inadequate to meet the pressure on the college's resources and the rising expenses of lectures and tutorial fees, equipment, laboratory material, and building maintenance. Up to now the nurses themselves have made good the deficit, but they cannot continue to foot the bill. Is this valuable work to be restricted for lack of funds?

If what the medical profession required of our nurses today were a blind unthinking obedience, such an eventuality might be of no great consequence. But the advances of medicine, and the obligations of the Health Service, make this out of the question. Today the doctor needs a colleague who will follow his line of reasoning, will realise the whys and wherefores of his treatment, and note the significance of untoward symptoms. He needs, besides, someone who can inspire her own subordinates and infuse them with the team spirit and her own keen sense of loyalty. A nurse's working life is not as long as it should be, but how much she can do, if properly prepared for her task, to fashion the generation who will come after. For this reason we cannot ignore the importance of further training for posts of leadership in nursing.

Here is something which is not paid for by the National Health Service. The educational work of the Royal College of Nursing was founded and developed by nurses, who treasure its creative independence, and we are appealing for £500,000 to put this work on a firm financial basis. The nurses themselves have under taken to raise half the sum and everywhere—in Scotland, in Northern Ireland in England and Wales—they are

SIGNIFICANCE OF COLOURED LINEÆ DISTENSÆ

SIR,—On reading Dr Simpson's letter (Sept 23) it occurred to us that these lineæ developed without clinical evidence of endocrine imbalance We therefore investigated all the patients in the pleural effusion unit of this hospital—56 men and 37 women—who are suffering from tuberculous pleural effusions, minimal pulmonary tuberculous lesions, or tuberculous ascites Their ages range from 14 to 43 years

Of these 93 patients, 39 (23 men and 16 women) bear red or purple lineæ—an incidence of 41.8% (men 41%, women 43%) The average gain in weight of the group with lineæ was 4.7 lb per month (men 4.3 lb, women 5.25 lb), while that of the group without lineæ was 2.2 lb (men and women 2.2 lb) Further, the smallest average gain per month in the group with lineæ was 1.5 lb, and none of the 18 patients gaining at less than this rate developed lineæ The distribution of the lineæ is usually over the loins, hips, sacrum, and lateral aspects of the upper thighs, the lineæ usually lie horizontally

We have also recently seen patients suffering from conditions other than tuberculosis who had developed coloured lineæ during a period of rapid gain of weight None of these patients showed clinical evidence of endocrine imbalance Could not the lineæ be caused by rapid increase in weight combined with local trauma from pressure and stretching of the skin? Does Dr Simpson consider that hypersecretion of adrenal cortex hormones is responsible for this high incidence of red lineæ distensæ in our patients?

Queen Mary's Hospital
Sidcup Kent

N F CROFTS
N K MACRAE GIBSON

** This letter has been shown to Dr S L Simpson, who replies as follows

Similar findings have been reported from Colindale Hospital by Hurford and Snell¹ who established that in a group of male patients with pulmonary tuberculosis, aged 12–26 the incidence of coloured lineæ distensæ was 45% They noted, as I had with adipose gynandrium, that after months or years the red lineæ became white, and they referred to previous accounts of which three are particularly relevant Allesandri² in 1931 described such striæ with pulmonary tuberculosis and believed that they appeared in young patients because of their more active endocrine glands and that they developed during exacerbation of the disease with increasing toxæmia Robertson and Goodall³ described such striæ occurring in the course of typhoid, dysentery, rheumatic fever, septic wounds and lymphadenoma (to which Hurford and Snell add 1 pneumonia 1 asthma 2 dysentery 1 tonsillitis, and 1 appendicitis) In 1928 Parkes Weber⁴ postulated as possible causes such factors as stretching of the skin rapid growth at puberty, and disturbed pituitary function during toxæmia

Now what does all this evidence mean? It is clear that red or purple lineæ distensæ may appear in the course

- 1 Hurford J V Snell W E *Tubercle* 1943 24 16
- 2 Allesandri C *Riv Pat Clin Tuberc* 1931 5 635
- 3 Robertson J D Goodall E W *Proc R Soc Med* 1931–32 25 213 803
- 4 Weber F P *Brit med J* 1928 1 255 *Urol cutan Rev* 1932 36 731

of a variety of infections, with a high incidence among tuberculous adolescents and young adults, and that during the development of the lineæ increase of weight is common though not necessarily present We know too, that red lineæ distensæ are very often found in Cushing's syndrome, a disorder associated with hypersecretion of 'Cortisone' or a cortisone like substance⁵, in pregnancy where a similar hypersecretion has been proved⁶; in adipose gynandrium and gynism, syndromes whose nature is still in doubt, and during puberty in certain constitutional endocrine types accepted by many as normal On the experimental side we have the classical adaptation syndrome experiments of Selye, and the work of Dougherty and his colleagues,⁷ indicating the importance of the adrenal cortex in the production or augmentation of immune processes On the therapeutic side we have the work of Sprague and his associates previously referred to (Sept 23, p 415), which appears to exclude the post-propter argument, and accumulating exploratory knowledge of the usefulness of cortisone or ACTH in some infections

Surely all this indicates that coloured lineæ distensæ can be interpreted fairly confidently as a manifestation of the hypersecretion of cortisone and cortisone like substances by the adrenal cortex The valuable additional evidence published in your columns seems to me to strengthen this view Incidentally, the high incidence of such lineæ in young patients suffering from various forms of tuberculosis would appear to raise the question of the place of cortisone or ACTH as an adjuvant to therapy, and it is fortunate that the adverse effect of cortisone on experimental tuberculosis, recorded by Dr D'Arcy Hart and Dr Rees (Sept 23), appears at this moment

MASS MINIATURE RADIOGRAPHY

SIR,—I found Dr Beynon's letter last week most interesting Both mass radiography units in the Oxford region have been using this no undressing technique, exactly as described by him for just over twelve months following on trials of the method in June 1949

The trials were carried out by Dr W T Bermingham then director of the Northampton unit, and by myself, being both concerned to enhance the appeal of mass radiography and aware that similar techniques had been in successful use in other countries for some years The films showed no falling off in quality compared with those previously produced by orthodox methods, and the technique was adopted, with confidence, for routine use

When the results of "repeat" surveys conducted in the past year are to hand, a better assessment of the method will be possible It is still regarded as subject to review, though from the viewpoint of appeal it has already proved of great value, and in several other ways has contributed towards simplifying the present somewhat cumbersome methods of mass radiography

THE "UNESTABLISHED" PRACTITIONER

SIR,—Principals with inadequate lists, assistants without a view to partnership and other unestablished general practitioners comprise a section of our profession for which too little is being done It is widely recognised that the arrangements for entry into general practice as a principal are at present grossly unsatisfactory It is extremely difficult to obtain an assistantship with a view, there are insufficient executive council vacancies to satisfy the demand, and in most parts of the country, the outlook for the "squatter" is bleak Many assistants face poor prospects and undesirable conditions of employment, while the entrants into general practice who have achieved the status of principal, but who have

- 5 Forbes A P Griswold G C Albright F *J clin Endocrinol* 1950 10 230
- 6 Vennart E H *Endocrinology* 1946 39 205
- 7 Dougherty T F Chase J H White A *Proc Soc exp Biol N Y* 1948 58 135

only small lists of patients, are commonly finding that they have little hope of significantly increasing the size of their practices within a reasonable time

Little is being achieved by the numerous individual complaints which are being expressed both in private and in the medical press. A growing number of "unestablished" general practitioners who have been discussing the state of affairs outlined above have come to the obvious conclusion that doctors who are placed in the unfortunate circumstances to which I have referred should get together in order to present their case for a "square deal". An open meeting has therefore been arranged and will be held at the Russell Hotel, W.C.1, on Wednesday, Nov. 29, at 8.15 P.M. It is hoped that doctors concerned will endeavour to attend this meeting, as it is clearly important that the views of as many as possible should be heard and discussed.

A statement on the professional problems of assistants and other "unestablished" (or inadequately established) general practitioners has been prepared. This statement also contains suggestions by which improvements for this section of our profession could be effected. I should be pleased to send a copy to anyone interested.

CARE AND MANAGEMENT OF LABORATORY ANIMALS

SIR,—In 1947 we issued the UFAW Handbook on the Care and Management of Laboratory Animals, edited by Prof. A. N. Worden, M.R.C.V.S. May we again appeal to all persons interested in laboratory animals to send us suggestions for the improvement of the handbook and any additional information which has come to their notice? The subjects on which information is required are:

The training of animal technicians, animal houses and animal rooms, rabbits, guinea-pigs, rats, mice, voles, hamsters, hedgehogs, ferrets, frogs, and other amphibians, fish, anthropoids, dogs, cats, goats, poultry, canaries, pigeons, or any other species of animals used for scientific purposes.

Subject matter can be conveniently forwarded to us grouped under the headings of anaesthesia, euthanasia, supply and breeding, feeding and watering, general management and hygiene, transport by sea, land, and air, and animal behaviour and psychology.

POSTURE

SIR,—In his letter of Sept. 30, Dr. Barlow quotes from an article by Prof. Raymond Dart¹ in which he discusses "the muscles which look after the relationship of the head with the vertebral column in man". Dr. Barlow may not be aware that Professor Dart has acknowledged indebtedness in this connection to a pamphlet which I published in 1937. At that time I wrote:

"An examination of a schema of the base of the skull showing the plotting of all muscles therein inserted will show that, while there is a preponderant mass of muscles inserted posterior to the foramen magnum, there is, anterior to the foramen magnum, a very feeble grouping of muscles. Observations of the living subject will at once reveal that the common misuse of the semispinalis capitis, the splenius capitis, the sterno-mastoid, and the trapezius muscles leads to a retraction and depression of the back of the head and an overbalancing of the primary group of muscles whose function is to maintain the relation of the head to the cervical spine."

The group of muscles which I named primary, inasmuch as I claimed that their action determined all further

relationships in living man, comprised the atlas occipital, axis occipital, and atlas-axis muscles, all taken together.

I am not interested in claiming any credit for myself in having made this observation, but I am most anxious that credit should be given to Mr. F. Matthias Alexander, whose teaching showed me that experience in the employment of his technique enabled an investigator to obtain the advantage described in the title of my pamphlet—namely, a "Reorientation of the View Point upon the Study of Anatomy"—and thus the attainment of means whereby a person might make constructive observations on the fundamentals of human physiology.

MUNGO DOUGLAS

THEORY OF BARBITURATE ACTION

SIR,—I thank Mr. Crossland (Oct. 21) for his interest in the theory I put forward in your issue of Oct. 7. His method¹ is to estimate the acetylcholine (ACh) protein complex in the brain, which he states has no physiological ACh action. It seems that it may be formed by resynthesis of the ACh previously hydrolysed by cholinesterase.² This complex might thus be a depot for ACh, and, in the presence of thiamine, might be made available as required by the central nervous system. Therefore, one might expect the "store" of ACh complex in the brain to be increased whenever the ACh content of the cerebrospinal fluid (C.S.F.) is decreased by any interference with its metabolism—e.g., by narcotics or general anaesthetics.

Whatever the accuracy of this theory, certain facts need to be explained: (1) the diminished production of ACh in the stomach and intestine perfused with a barbiturate solution, especially on stimulation of the vagus nerve³; (2) in man, the neutralisation by barbiturate of the diuretic action of thiamine⁴; and (3) the inhibition by barbiturate of the growth of staphylococci (which need pre-formed thiamine) in broth—an inhibition that can be reversed by the addition of thiamine to the medium.⁵ (This observation was made since I last wrote.)

I think all these constitute good evidence that barbiturates and thiamine are antagonists. The increase of ACh in the C.S.F. after epileptic attacks, mentioned by Mr. Crossland, might well be due to decreased production of cholinesterase.

Dublin

H. W. DALTON

THE R M B F

SIR,—Again I appeal to members of the medical profession, whether subscribers to the Royal Medical Benevolent Fund or not, to send a donation for Christmas gifts for beneficiaries of the fund, all of whom are facing a time of special difficulty owing to the high cost of living.

Last year it was decided to send each beneficiary a gift of £10, but the donations to the Christmas gifts fund were not enough to meet the cost, and half of this sorely needed help had to be taken from general funds. This cannot be done this year owing to the present heavy calls on the fund.

I hope that there will be a generous response to this special appeal for Christmas gifts, which are not only desirable but necessary and are most deeply appreciated. Let us warm the hearts of the beneficiaries of the fund by showing them that they are not forgotten by their more fortunate colleagues.

Obituary

JOHN HUBBACK ANDERSON

C.M.G., C.B.E., M.D. MELB., F.R.A.C.P.

Colonel Anderson, physician to Ruthin Castle, died on Nov 4 at the age of 67.

He was born in Urana, New South Wales, and educated at Longford Grammar School in Tasmania. For a time he worked in a lawyer's office in Launceston, so he entered Osmond College, Melbourne University, in 1904 rather older than the average medical student. He won the respect of his younger fellow students by his high moral and spiritual standards, he took part in all the college activities and rowed bow for the college eight. After qualifying in 1908 he continued at the university as senior demonstrator of anatomy, taking the M.D. degree in 1911. After a period as assistant physician at St Vincent's Hospital, Melbourne, he settled in practice at Benalla, in Victoria, but he enlisted in the Australian Imperial Force at the beginning of the 1914 war. From Gallipoli he was invalided with severe dysentery, but after a time in Egypt he accompanied the Australian Forces to France as D.A.D.M.S. Later he was transferred to Australian headquarters in London, where he became the right-hand man of Major General Sir Neville Howse, V.C. Thus another generation of Australian doctors came under the influence of his just and upright honesty in dealing with difficult situations and men. For his overseas service he was twice mentioned in despatches and he was appointed C.M.G. and C.B.E.

After three years in his old post in the Melbourne anatomy school, where he also acted as professor in the absence of Prof. R. J. A. Berry, Anderson returned to England with his wife and two children. In 1924 he joined Ruthin Castle Clinic as assistant physician.

He served the clinic and the local community until his death, except for the years of the late war when he was called back to act as liaison officer in London between the Australian Commonwealth Medical Forces and the War Office. This work was a great strain on a man of his years and conscientiousness. He had to attend innumerable committees and conferences and twice during the war he flew to Australia. His war-time association with Australia continued afterwards and he acted as London correspondent of the *Medical Journal of Australia*. He felt greatly honoured by his election to the fellowship of the Royal Australasian College of Physicians in 1947. His honesty, frankness, and good humour made him an excellent chairman and interpreter of the sense of meetings, and he had a fine record of service in North Wales. Besides his work for the British Medical Association he served as district commissioner for Boy Scouts and was largely instrumental in raising funds for building the local scout hall, he was president of the local branch of the British Legion, and as a justice of the peace he became chairman of the Ruthin children's court.

S. W. P. writes: Anderson came of a robust North of Ireland stock. He learned many sound views from his father, the late Dr. J. F. Anderson, of Woodend, Victoria, and he used to say he learned much from his patients while in private practice before the first world war. His training made him a clear and accurate thinker, and a kind good doctor. Tributes from former patients all express a sense of personal loss at his passing. Nothing was too much trouble for him, the smallest detail of treatment the little more that made for his patients' comfort and security, all received his closest attention. Another group of men scattered throughout the world will mourn the death of Jock Anderson: students he taught to think clearly and accurately, fellow workers impressed by his shining example of honesty and hard work, and friends who trusted his straightness and loyalty.

Anderson married Ruby Clare Moffatt in 1919. She died in 1937, and he is survived by a son and a daughter. His younger brother practises ophthalmology in Melbourne.

SAMUEL THOMPSON ROWLING

M.D. LEEDS, F.F.A.R.C.S.

Dr. S. Thompson Rowling, visiting anaesthetist to the Leeds General Infirmary, who died on Oct 12, at the age of 76, was a pioneer in his specialty and one of the city's foremost general practitioners. He also held the appointment of lecturer in anaesthesia in the University of Leeds.

The son of Samuel Rowling, he was born at Headingley and educated at Leeds Grammar School, Yorkshire College, and Manchester University. In 1896 he graduated at the old Victoria University, and after holding house-appointments at the Leeds General Infirmary he settled in practice in the city. He was appointed anaesthetist to the Infirmary in 1910. In 1920 he took his M.D. and in 1935 his D.A. He was elected to the fellowship of the Faculty of Anaesthetists in 1948.

R. C. L. writes: "Besides his medical work Rowling found time to interest himself in the Church Army, and the St. John Ambulance Brigade. A non-smoker and total abstainer, he was one of the most highly valued lay preachers in the diocese. His inventions included the well-known Rowling chloroform bottle, and more recently he was concerned in the production of the Ringrose Rowling Harbord carbon dioxide indicator. In the most serious anaesthetic emergencies he was always level-headed and courteous, and his services were valued by the surgeons with whom he worked."

He leaves a widow and three children, two of whom are doctors.

FREDERICK HENRY DODD

M.R.C.S.

Dr. F. H. Dodd, who died at his home on Aug 17, was known for his outstanding work in the residential care of children with psychological problems.

Qualifying from Guy's Hospital in 1914 he became interested in psychiatry, and especially child psychiatry. After holding a resident post at the Evelina Hospital, London, he became an assistant physician to the Queen's Hospital for Children, and later first assistant in the children's department at Guy's Hospital under Dr. Charles Cameron. He was also on the staff of the Tavistock Clinic.

During the 1914-18 war he served as a captain in the R.A.M.C., and he continued to serve on medical boards as a heart specialist. His was therefore no narrow specialisation: throughout his career he retained his interest in general medicine, and he always worked with both adults and children.

After his marriage he and his wife for 25 years ran a private residential school for children who had failed to make progress in a larger school. In 1940 when the school was moved to Dorset, he also served as psychiatrist to hostels for evacuee children throughout North Dorset. After the war he resumed a consulting practice in Sherborne, and only retired from running his school in 1949. He then went to Oxford, where he and his wife, a daughter of the late Professor Lodge, had many friends, and here he had hoped to continue his consultant practice.

E. M. C. writes: Dr. Dodd believed that in all work for children with difficulties it was important to recreate the family setting and feeling. His was not a free school in the sense of no discipline and regulations, but it was headed by Dodd, who with his wife shared their family life closely with all the children. They relied far more on a broad basis of cultural living and education than on specific methods or on clinical psychotherapy. His book *Common sense Psychology and the Home* in which his wife collaborated, expresses much of his personal philosophy. Here he succeeded in giving a sense of direction to parenthood. He always worked with the child as a whole body, mind, and spirit, and in close contact with the parents. Some children placed in his care with misgivings because they had always been ill were never ill with him. This was not the work of a magnetic personality but of a dedicated life, deeply rooted in spiritual faith.

His widow survives him, with three sons and one daughter.

DR FLORENCE LOUIS

"EARLY in the war Dr Louis began to undertake work for London coroners," writes W B P "In my court and that of Neville Stafford she found as colleagues Spilsbury, Donald Teare, and Francis Camps, and she was at once accepted as one of them. To this work she brought an original talent, for she never ceased from being a physician. When she described the conditions that she had found after death, whether the death was simple and natural or was a violent one, she was describing a patient rather than an inanimate object upon which she had made an examination in the post-mortem room. This quality eased the minds of relatives who heard her give evidence, to some of her colleagues in coroners' courts, it was a new approach to the matter. Among the members of the team of pathologists who meet each other frequently in the courts of two coroners in London she is missed not only as a friend and a most charming person, who always remained a woman, but as a source of up-to-date information upon any clinical problem with which they were faced. As a witness before the coroner or at the Central Criminal Court, she was clear in her language and unshakable in cross examination because of her honesty of expression. She never trimmed her evidence to fit what might appear to others as being the most likely combination of facts that would make a consistent whole. In my experience, on two occasions after she had held to her opinion, she turned out to have been right, on no occasion was her conclusion found to be wrong."

The *Scottish Chemists Index of Modern Remedies* (fifth series) is designed like its predecessors, to provide in compact form 'a guide to the prescriber and a ready reckoner to the pharmacist'. Into its 86 pages is compressed a remarkable amount of up-to-date information concerning not only proprietary preparations but also the new *British Pharmacopoeia B.P.C.* and *National Formulary*. The index price 5s., is obtainable from the *Scottish Chemist* 210, Albert Drive, Pollokshields Glasgow S 1

Notes and News

MANX CRISIS

THE withdrawal from the health service of 33 of the 40 chemists on the Isle of Man marks the climax of a long dispute with the Manx Health Services Board. The quarrel began when the board decided to effect an economy by levying a 6d charge on all prescriptions, and a fee on containers. An order to this effect was passed by the Manx parliament, and came into force on Oct 1. The money was to be collected by the doctor or chemist who dispensed the medicine, but the Medical Society and the Chemists' Association strongly opposed it and instructed their members to disregard it. They say that it is impracticable, and that the Advisory Council should have been consulted before it was introduced. The latest development—withdrawal of the chemists from the service—was precipitated by the alleged refusal of the Lieut Governor to receive a chemists' deputation, or to allow the matter to be referred to arbitration. It is noteworthy that it was the doctors' support which decided the chemists' attitude six weeks ago when they were preparing to yield to the board "under protest."

SUBJECTIVE JUDGMENTS

THE use of man as a meter to measure his surroundings was the subject of a Conference on Subjective Judgments held at University College, London, on Oct 14. Nearly 200 physicists, engineers, and psychologists discussed experimental techniques using the taste, touch, sight, smell, and hearing of human 'subjects'. The conference divided itself into two opposing points of view—the 'cants,' who maintained that measurement of sensations was impossible and pointed out fallacies in experimental methods, and the 'musts,' who insisted that however philosophically unsound their techniques might be considered they served their purpose if they gave data of precise operational value.

A topic which raised much discussion was the use of "trained observers," who are intelligent people capable of understanding the nature of the observations required of them. Such observers can give assessments readily and can report their readings with reliability. Their observations can be shown to agree at selected points with those of a random selection of the general public. Many speakers thought that this was a dangerous theory and there were quips from the 'cants,' that the observers were trained to give the required answers. The 'musts,' however, pointed out that if they had to employ, say 500 observers for every experiment, little or no progress would be made in the work.

The conference was arranged as a private venture largely on the initiative of Mr R G Hopkinson, PH.D., (Building Research Station, D S J R), and was designed to bring together workers from different fields who do not normally meet but who are concerned with subjective judgments. The proceedings will not be published, but the main speakers have papers describing their techniques which may be available on request. Further information may be had from Dr Hopkinson, Building Research Station, Bucknalls Lane, Garston, nr Watford, Herts.

NEED

THE activities of the National Assistance Board are remarkable in their scope. Its latest report¹ shows that at the end of last year no fewer than one in thirty of the total population were wholly or partly dependent on it for regular financial assistance, four fifths of the recipients being old, infirm, or sick. Supplementary allowances were paid to 80 000 of the 850 000 persons receiving sickness benefit under National Insurance at the end of the year, and a further 100 000 allowances were paid to sick persons not entitled to benefit. 9000 unmarried mothers and 34,000 deserted or separated wives were supported or assisted and pocket-money at the rate of 5s weekly was paid to about 10 000 hospital patients without other resources. During the year the board made 1,660,000 single payments to meet urgent but temporary requirements of the most varied kind and £383 000 was spent on 'exceptional need grants' mainly for clothing and bedding. The board's officers did not confine themselves, however, to providing funds but were able to bring their influence and experience to bear upon innumerable domestic

problems. A landlord was prompted to repair a dilapidated kitchen, a gas meter was moved at the board's instigation to a position where it was more accessible to an elderly rheumatic lady, a solicitor was found willing to article a blind law graduate, and Mr Sandy Macpherson was asked to play a request item for a couple of blind octogenarians. These and many other similar episodes quoted in the report suggest that the board may frequently be able to cope with situations which baffle the general practitioner.

STUDENTS IN ACTION

THE political bias of the International Union of Students has at last exhausted the patience of the British Medical Students' Association, which decided at its annual general meeting in Manchester last week to set up a non political international medical bureau open to all medical student bodies. The executive of the B.M.S.A. was able to report on a very successful year, and to obtain the delegates' approval of the plans made, in conjunction with the National Union of Students, for the creation of a residential reablement centre for university workers and students with tuberculosis. The meeting also discussed the compulsory house appointments, and asked that the "appointed day" be deferred until Oct 1, 1954, that the housemen should have at least 20 beds in teaching and 30 in non teaching hospitals, and that Colonial hospitals be recognised for the purpose of these posts, to enable Colonial students to complete their training in their own countries. It was decided to appoint a permanent subcommittee on medical education, and to issue a handbook for medical students.

Prof Geoffrey Jefferson, F.R.S., was invited to become honorary president for the coming year, and Mr Robin Coppock, of Cardiff, succeeded Dr Peter Diggory as student president.

University of Oxford

Dr Alice Stewart, acting director of the Institute of Social Medicine, is carrying on the duties of the professorship of social medicine during the Michaelmas term.

University of Edinburgh

Prof Ian Aird is to deliver a Macarthur postgraduate lecture on Friday Dec 15 at 2.30 p.m., in the surgery lecture theatre. Professor Aird will speak on the Surgical Exposure of the Pancreas.

Royal College of Surgeons of England

At a meeting of the council on Nov 9, with Sir Cecil Wakeley the president, in the chair, Mr W Kelsey Fry was admitted as a co-opted member of the council. Mr K W Starr was elected and admitted as a member of the court of examiners for one year and Mr Ralph Marnham and Prof F A R Stammers were elected members of the court of examiners. Prof John Kirk was elected an examiner in the forthcoming primary fellowship examination to be held in Cairo in January, 1951.

The appointment of Dr Howard K Gray, of the Mayo Clinic, as a Moynihan lecturer was reported. Prof Francis E Stock, of Hong Kong, was elected a Hunterian professor. The re-election of Mr F Masina as Proffit student was reported. The council received from Dr G M Ververs a gift of a cast of the Cheselden medal.

Diplomas of membership were conferred on those whose names were published last week (p 546) as recipients of the L.R.C.P.

The following hospitals were recognised under paragraph 23 of the fellowship regulations.

The Waikato Hospital Hamilton New Zealand Birmingham and Midland Ear and Throat Hospital junior registrar. Royal Victoria Hospital, Bournemouth 4 house surgeons all orthopaedic house surgeons (for 6 months). Archway Group London registrar 2 junior registrars 3 house surgeons 1 orthopaedic house surgeon. E.N.T. registrar Hackney Hospital London registrar 2 house surgeons (for 6 months).

Royal Faculty of Physicians and Surgeons of Glasgow

At the annual meeting of the faculty, on Nov 6, the following office bearers were elected for the ensuing year: president Mr W W Galbraith, visitor, Mr Andrew Allison, hon treasurer, Mr Matthew White, hon librarian Dr A L Goodall, representative on the General Medical Council, Mr Andrew Allison.

International Hæmophilia Society

This society is to hold an open meeting at 2.30 p.m. on Sunday, Nov 26, at 34, Eccleston Square, London, S W 1.

Medical Practices Compensation

Claims for compensation for the loss of the right to sell the goodwill of practices should be submitted by the end of this year. Claims submitted in the first two months of next year will be accepted only if the Minister of Health is satisfied that the delay was due to special circumstances. No claim will be accepted after Feb 28.

N A P T Prize

The National Association for the Prevention of Tuberculosis is offering a 100 guinea prize for an essay embodying the author's ideas and proposals for the improvement of the control of tuberculosis throughout Britain. The competition is open to doctors of ten years standing who are working as tuberculosis officers, chest physicians, or sanatorium medical superintendents in the United Kingdom. Further details can be had from the secretary general, N A P T, Tavistock House North, Tavistock Square, London, W C 1, to whom essays should be sent by March 1.

Conference of Assistant Nurses

At the third winter conference of the National Association of State Enrolled Assistant Nurses, held in London on Nov 8, criticisms were expressed at the continued use of the term "assistant". Mr A Blenkinsop, parliamentary secretary to the Ministry of Health, said that the percentage of passes in the 195 assistant-nurse training schools with their 2000 students was high. Definition of the status and scope of State enrolled assistant nurses is one of the matters which the association is taking up with the Ministry. The association is also anxious that S.E.A.N.s should have opportunity for promotion and it has protested against the General Nursing Council's recommendation that S.E.A.N.s should be senior to student nurses only until the latter have passed their preliminary examination, which many S.E.A.N.s have themselves passed. Dr C H C Toussaint spoke to the conference on the domiciliary management of tuberculosis cases. At the conference dinner, Dr Marjory Warren, president of the association was in the chair.

Society of Apothecaries of London

A course of ten postgraduate lectures on modern methods of diagnosis and treatment is to be held on Dec 4-8.

Art Therapy in Clinics and Hospitals

A conference of art therapists in clinics and hospitals will be held on Dec 2, at 2 P M, at 39, Queen Anne Street, London, W 1. It will be mainly concerned with plans for future co-operation, and training standards. The size of the meeting is limited to 50, and applications should be sent to the conference secretary at 39, Queen Anne Street.

More Hospital Beds

In the two years from July, 1948, to the end of last June the number of staffed hospital beds in England and Wales increased by nearly 15,000. Of a total of about 514,000 beds, 470,000 were staffed at the end of this period. This is announced by the Ministry of Health, which states that hospital nursing and midwifery staff has increased by 24,000 (16,000 full time, 8000 part-time) to a total of nearly 160,000 (135,000 full time 25,000 part-time). Increases have taken place among all grades, including student nurses, midwives, and pupil midwives. There are now 7000 more student nurses, the total being 49,000, this is a new record.

British Medical Association

The association is offering the following scholarships for "research in any subject (including State medicine) relating to the causation, prevention, or treatment of disease". Ernest Hart scholarship (£200), Walter Dixon scholarship (£200), and four other scholarships (each of £150). In addition, the Insole scholarship (£250) is offered for research into the cause and cure of venereal disease.

Each scholarship is tenable for one year from Oct 1 1951, a scholar may be reappointed for not more than two additional terms. Scholars may be members of the Armed Forces or may hold a junior appointment at a university, medical school, or hospital, provided that this does not interfere with the research. Applications should be submitted by March 31 1951 to the secretary of the association, B.M.A. House Tavistock Square, London W C 1.

Appointments

BATES T J N M B Dubl, D.P.M. non resident psychiatrist, Winwick Hospital Lancs.
BREARLEY, B F M.A., M B Camb M.R.O.P. consultant general physician, Preston Royal Infirmary Sharoe Green Hospital and Chorley hospitals.

STUDY OF DELINQUENCY *

D H STOTT

M.A. Camb, Ph.D Lond.

I SHALL take as my theme What contribution has contemporary psychology to make to the prevention of delinquency and the cure of delinquents?

It is well to review first how much the psychologist and the knowledge at his disposal is used. As regards prevention the answer is quite simply. Hardly at all. Neither the public nor the State have yet begun seriously to deal with the child in his pre delinquent phases. Public concern is limited to punishing him when he dares to force his unhappiness upon us.

Quite unnecessarily we allow unhappy children to remain unhappy, either because we are insensitive to the signs, or regard them as mere naughtiness or as just part of a child's nature. At present the school-teacher, for instance, who is in the best possible position to spot the unhappy child and potential delinquent, receives no training in how to do so.

Quite unnecessarily also we allow children to remain, year in year out, in human situations so deleterious that their only defence against insanity is to eschew all sentiment and all affection, and to develop that lack of finer feeling and loyalty which is misnamed "moral defect". When such types become delinquent society is up against a tough problem.

What is worse, through ignorance and our own insensitivity we are manufacturing criminals, putting children in situations where there is a reasonable prospect of their developing into immoral types. Our knowledge about how criminals are made has only been available in recent years, and for the most part has not yet got through to the administrator, the social worker, the magistrate or the legislator. For example, in allowing the parent to bring his child to court as "beyond control" we provide the machinery for the child's being rejected, and lend substance to the anxiety-creating threat of "putting away".

SHORTCOMINGS OF THE ADMINISTRATOR

My observation of the large number of adolescent delinquents who had passed their childhoods in institutions has made me spend some time recently in examining what happens to them there.¹ I found that, for administrative convenience, it is quite a general practice for parentless children to be raised in a residential nursery until they are three, and in a toddler's home until five, at which age they are transferred to a home for children of school age. The five year-old, in so far as it has had mother figures at all, has had at least three different ones. It has been taught by bitter experience never to attach itself deeply to anyone. This is what the matron of a toddlers' home said to me:

"Nursery children are altogether different from other children, they are always on the defensive they never give, they take. It is a long time before they will play properly with other children, they are more self-contained. It takes a long time to get underneath a nursery child they don't trust you."

I have heard a very sincere Children's Officer suggest that a difficult child should be placed with a good foster-mother, for a few months only until he settled down, and then be removed from her—as if his difficult behaviour was merely a question of getting him accustomed to a regular daily routine. Again, it is current practice, owing to the shortage of space in Children's

Homes and owing to legalistic ideas as to the parent's primary responsibility irrespective of the good of the child, to try to force unsuitable and unwilling mothers to have their children back again.

Let me quote now very extraordinary example of a problem which all housing authorities have to face. It is of a family of bad rentpayers who had been twice evicted, and refused further council accommodation on that account. Man, wife, and four children were forced to live in one small room which had been allowed them by a charitable acquaintance. No attempt to rehabilitate the family was made. Authority took the view that it was their fault, they were made to stew in their own juice, and the result was that one of these children and two others of the family who were forced to live elsewhere became delinquent.

SHORTCOMINGS OF THE PSYCHOLOGIST

I do not want to lay the blame for the manufacturing of criminals upon our public administrators. They have no doctrine to work upon, and so the good and the evil that they do is a matter of chance—the chance that any particular officer is a humanly feeling person in a human mood, who is not overwhelmed by other administrative pressures. It is rather the fault of the psychologist that he has not yet properly expounded or popularised recent knowledge about the effect of the human environment upon character, nor have we embodied it in a procedure which the administrator and social practitioner can utilise. We must evolve procedures which are just as much an inescapable routine as a medical examination, and which would make the failure to consider the emotional situation of a child just as reprehensible as a dereliction of duty as subjecting a child to physical hardship. I shall therefore lay my chief emphasis upon this subject of procedures for studying human beings and human relations.

In the main, these techniques are not yet in existence. The traditional psychiatric examination, at the best discovers nothing that the most ordinary inquiry into the behaviour of the patient would not reveal, and at the worst is the subject of justifiable ridicule by those who have to read, and are expected to act, upon its findings. I have in mind a case where a Children's Department is nonplussed by the report of two clinicians upon a boy, one of whom described him, correctly, as highly disturbed, the other as perfectly normal. The point about a consulting room interview is that whereas it *might* be revealing, there is no guarantee that it will be so. The child is seen in only one mood, and in only one situation. Nor do I believe that any projection-technique, however valuable for giving hints as to essential attitudes, can ever be a substitute for the direct study of actual behaviour. And the more remote any specimen, consulting-room behaviour is from the usual range of a person's activities, the bigger the chance that it will be unrepresentative, and the greater the need to prove that the test means what it is meant to mean. The procedure of direct observation has these drawbacks to a greatly lesser degree. As I hope to show later it is easier to interpret behaviour in real life than in artificial situations.

Since therefore, it is likely that a lot of work will be done in the next few years on techniques of observation, and, as I hear, similar work is being started in America, I should like to say something about the principles governing such techniques.

CHARACTER TRAIT OR SITUATION-ATTITUDE?

The first thing to be clearly recognised is that the concept of the character trait does not correspond with reality. The old schedules asked the observer to state whether a child was "coöperative or uncoöperative," "cheerful or depressed," "lazy or hardworking," as if

6639

he was one or the other of such alternatives at all times to all people. In the course of my study of boys in approved schools I did draw up such a schedule of traits so that I could discuss each boy with his housemaster and instructors. I was astonished to find what different opinions were forthcoming. To one man a boy was endowed with all the virtues, to another with all the vices. This was not in the main due to the well known halo phenomenon of personal judgments—the tendency to paint people we like white and those we dislike black, these lads did behave differently to different people, they did act as the saints or the sinners that they were painted.

In the end I had to scrap the whole schedule of trait assessments, instead I began to study variations in behaviour according to the type of situation. "A," I noticed, was a delightful personality so long as he did not have to obey an order. "B" was a fine craftsman, except that when in a bad mood he could not make the simplest measurement. One might say in general that *the response varied according as any given situation did or did not offer the prospect of satisfying a basic psychic need*. And the quality of the reaction depends upon the expectation of fulfilment which the person has come to have as a result of his experience of previous, somewhat similar situations. This may sound rather theoretical, but rather more simply, one might say that people develop habits of reaction, or attitudes to situations of a certain type. People with largely unhappy human experiences tend to assume that everyone will betray, cheat, desert or rebuff them—hence a pervasive attitude of misanthropy which looks like a trait of character. But some of my boys would mistrust women more than men, and vice versa, some would mistrust all adults but display a desperate loyalty to their fellows. These complications can be embraced by the concept of the situation-attitude but not by that of the trait, the bankruptcy of the latter concept, incidentally, being no better seen than in Allport's refinements which postulate the capacity of traits to die, to be born again, to metamorphose themselves or to come into activity or not for reasons of their own—the which acts as a warning not in our turn to elevate the situation attitude into a kind of little internal bogey man. It is merely a conative habit, and, I believe, obeys the laws of habits.

This view of the situation attitude as a habit has important bearings, which I shall mention later, upon treatment. Also, if one has studied the way a person tends to act in various types of situation, one is in a position to help him choose those situations which bring out the better side of his nature, or advise those who have the care of him in arranging for his future, shall we say, upon his licence from an approved school. And when it is realised how much a person's emotional health depends on the situations he meets, one sees how dangerous it is to make a prognosis in the abstract. This type of prognosis, which incidentally often does tremendous harm by discouraging people from persevering with a disturbed child, is seen, like most of the current notions about so called mental disease, as a concept recklessly borrowed from physical medicine.

For observational purposes I think the best way of preventing the concept of the situation attitude from developing into another mystical and ultimate thing in itself is to regard it merely as the summation of a number of bits of behaviour—bits of behaviour, however, which are classified according to a theory, that is to say, which have been selected in the light of what we know about the general potentiality for feeling and reacting that human beings possess. It is a question, then, of collecting the samples of behaviour which will enable us to make these inferences of situation attitude. The blind recording of behaviour, it cannot be too plainly stated, without any theory as a guide to signifi-

cance, is likely to result in triviality and to be of little use for diagnostic purposes.

By way of illustrating what I mean by this inference of situation attitude, or in other words the interpretation of behaviour, may I take the case of a five year old institution reared girl who was described by the staff as "aggressive"—a beloved word of child welfare people which can mean practically anything. This is how the house mother described her tempers. "She will go up into the bathroom and throw things out of the door one by one, slamming the door in between each article and saying 'I don't like nobody here'." She is better than she was. She used to say, 'I don't like nobody in this home. I only like myself'." The aggressiveness, thus seen in terms of actual events, reveals itself as an attitude of violent rejection. When I inquired about the same child's reaction to endearments the house mother said "She likes to be kissed when she goes to bed. You can't kiss her at any odd time. She wouldn't come for a kiss or a hug, but when in a good mood she will make no objection, in a bad mood she will shake herself free." One sees another aspect of the rejection and affection shyness. How pervasive this attitude was becoming, even in a child of five, is revealed in what would once have been described as a trait of contrariness and obstinacy. She would not only reject affection in itself, but the kindly ministrations of adults in all forms. "At one time—to quote the house mother again—if we were to ask her if she liked a certain thing, she would say 'No' as a matter of policy." Although a child of good appetite, she made a gesture of pushing away food, saying "Take it away, I hate that stuff." And (quoting again) "Sometimes you will find her stark naked by her bed saying 'I don't know what to put on' and tossing her clothes about. If we say 'Put your vest on,' she replies 'I don't know what my vest is'."

My point, in summary, is that these samples of behaviour tend to interpret each other. Viewed together, they enable the clinician not only to diagnose an attitude, but to estimate its strength, its consistency, and the degree of its spread or projection over a range of situations—to what extent, in short, it becomes a dominant pattern of reaction. And above all, the clinician has an objective measure of the child's progress. Much of the behaviour just quoted belonged to the first few months of the child's stay in the institution. The fact that the gestures of rejection were gradually being discontinued meant that she was learning to accept the affection of the house mother and her staff, in other words the treatment was being successful.

A GUIDE TO OBSERVATION

It is now time to refer to the "Guide to Child Observation" which I have prepared. Its full title is "Guide to Child Observation (Children in Institutions, 5-15 years)" and the following is an extract, taken from the part of the section "Attitudes to Staff" which is most relevant to the behaviour of the five year old girl quoted above.

Affection—Accepts and gives affection freely/always "coming for love"/demonstrative ("all over" people)/pretends indifference or independence/refuses affection avoids any intimacy.

Friendliness—Friendly, natural/unresponsive (cold, deep, 'you don't know how to take him'), cannot show appreciation ("takes things for granted").

Confidence—Talkative/quiet. Forward (opens conversation, tires people with constant chatter)/shy, aloof (does not make the first approach)/auspicious ('on the defensive').

This guide was evolved from a series of discussions which I held with house mothers and house fathers and their assistants—taking 20 children, spending an afternoon on each, and making notes upon the kind of things each child did, upon the way it behaved to the staff.

and to other children, how it played games, treated its possessions, and so on. The schedule gradually took on its present shape as a result of successive draftings, but it has yet to be seen how the staff of a home can use it independently. You will notice that general "blanket" descriptions are avoided as far as possible. Phrases like "Temper, bullying, nervousness" are used by people to describe astonishingly different kinds of behaviour. Tempers may refer to explosive inferiority-reactions, or to gestures of rejection, bullying can be more domineering and assertiveness, or a real desire to hurt, nervousness a tendency to compulsive movements, or high fears. While avoiding these popular clichés the schedule must be framed in language that the non-technician can follow, it is a question of selecting such expressions as will conjure up the image of a child *actually behaving in a certain way*.

It may be thought that for the use of institution staff this schedule is too complicated. But a picture of a personality, to be of value, must be a comprehensive one. And if all these queries are not laid out in black and white, the clinician would have to waste time and energy to putting them all by word of mouth, with the additional risk of leaving something out and so of not eliciting certain crucial facts. Also, once a member of a staff gets used to the schedule, he or she should be able to run through it quickly in respect of a particular child. Most important of all, familiarity with a guide such as this acts as a training in observation. On many occasions a house mother or house father has said, even as regards nail biting "He may do, I couldn't be sure. I must watch him."

For each category of person and situation separate guides would have to be drawn up by the study of sample groups. For instance it would be of tremendous interest to have one for children up to three years old. We would want another for children of five to fifteen living in their own homes (such, in a rough and ready way, as I developed for the systematisation of the home information in my study of boys in approved schools), and yet others for the study of parents and prospective foster parents.

Only by taking separate schedules for each category of person can one go into the kind of detail that will begin to yield really significant results. For example, my factors J 3 and J 4, "Father or Mother lacking in, or inconsistent in, Affection" are obviously inadequate to embrace all the inconsistencies, conflicts of attitude, guilty displays of over affection, insincere mouthings of fondness, deep affection which cannot express itself, and so on, that one finds in real live parents. My difficulty was, of course, to keep the whole life history of the boy, his present array of situation attitudes, and the characters of his parents within manageable proportions in one statistical summary. The original sheets actually had 256 factors, or over half as many again. Nevertheless, despite its inadequacy, it occurred to me that other clinicians might like to work on a similar schedule, both with delinquent and non delinquent cases. It would also be extremely interesting to see to what extent a random sample of ordinary youths tend to conform to the same reaction patterns or, alternatively, fail to score. Consequently I have had a number of blanks prepared, which I shall be pleased to supply to anyone who thinks of doing similar experimental work.

DATA FOR STATISTICAL ANALYSIS

I have so far stressed the practical need for these systematised observations—their use, that is to say, for diagnosis and for counsel. Their theoretical utility must be even plainer. Some acts and utterances lend themselves to easy interpretation, as instance the so called

aggressiveness of the five year old girl which I took as an example. But the inner or unconscious purpose of some behaviour is not at all obvious. Is bedwetting a symptom of a general anxiety, as sometimes assumed, or is it associated with a particular kind of unsatisfactory mother relationship? Is a lack of care for his appearance in a boy more often associated with nervous exhaustion, an indifference for the regard of others, a mood of going to the dogs, or an unconscious desire to annoy his parents? These questions can only be answered by the application of statistical techniques—which means that the variables must be defined with a reasonable objectivity. Once we can reduce our study of personality to quantitative terms, we should be able, if we can keep the mastery of our statistical steel, to advance to new certainties about human nature.

THE PSYCHOLOGIST'S TASK

Perhaps it is time I returned to my subject. To summarise the psychologist's rôle in the prevention of delinquency, it is to provide a routine for deciding what a child is like, and what kind of things he may be expected to do next, further, to sharpen the observation of those who have to do with children, so that the unhappy ones, the potential delinquents, can be spotted at an early stage, and finally to make the public, and parents in particular, and our administrators more particularly still, sensitive to the emotional needs of children.

The other side of the psychologist's work is the treatment, both of the pre delinquent and of the already delinquent. Here our record is anything but a bright one, and it will not be letting the side down to be frank about the present state of things. It is better that criticism should be voiced by psychologists among psychologists, than by those who doubt the value of psychology. And whether it be Sir Leo Page³ or I who draws attention to our weaknesses, it matters little, because all those who use our existing psychological services are only too well aware of them.

Just a week or two back a club leader told me how he had for some two years been taking a personal interest in an artistically gifted club member of his, who was very unsettled. The probation officer advised him to seek the advice of a well known clinic. After a single interview with the lad the clinician refused to see him again. It was too bad a case! In another case recently reported to me, the clinician, a supposed specialist in delinquency, rejected a delinquent boy, again after one interview, because he was uncoöperative. These instances reveal a fundamentally wrong view of treatment. One cannot expect every young delinquent to lie on a couch and spew up his innermost thoughts. We must recognise the fact that some delinquents are awkward people. Imagine what would be said of a family doctor who refused to treat a patient because he did not respond to his one and only prescription. A refusal to treat, or a picking and choosing of our patients, will only damage our reputation among the magistrates, the club leaders, or school teachers who are enlightened and humanitarian enough to refer a child for psychological advice.

Our essential error is that treatment is too clinic centred: there is a danger of developing a cult around the mystic belief that by some process of turning the patient emotionally inside out he will receive an inner cleaning—a process which, apart from its very dubious value, needs so many scores or even hundreds of interviews as to be quite irrelevant for our present delinquency problem. There is of course a place for the giving of insight by some outsider who stands apart from the world with which the lad has embroiled himself. It was

² In the statistical summary attached to Delinquency and Human Nature (ref. 1)

It is a question, then, of collecting the samples of behaviour which will enable us to make these inferences of situation attitude. The blind recording of behaviour, it cannot be too plainly stated, without any theory as a guide to signifi-

cance, is likely to result in triviality and to be of little use for diagnostic purposes.

By way of illustrating what I mean by this inference of situation-attitude, or in other words the interpretation of behaviour, may I take the case of a five year-old institution reared girl who was described by the staff as "aggressive"—a beloved word of child-welfare people which can mean practically anything. This is how the house mother described her tempers. "She will go up into the bathroom and throw things out of the door one by one, slamming the door in between each article and saying 'I don't like nobody here'. She is better than she was. She used to say, 'I don't like nobody in this home. I only like myself'." The aggressiveness, thus seen in terms of actual events, reveals itself as an attitude of violent rejection. When I inquired about the same child's reaction to endearments the house mother said "She likes to be kissed when she goes to bed. You can't kiss her at any odd time. She wouldn't come for a kiss or a hug, but when in a good mood she will make no objection, in a bad mood she will shake herself free." One sees another aspect of the rejection and affection shyness. How pervasive this attitude was becoming, even in a child of five, is revealed in what would once have been described as a trait of contrariness and obstinacy. She would not only reject affection in itself, but the kindly ministrations of adults in all forms. "At one time—to quote the house mother again—if we were to ask her if she liked a certain thing, she would say 'No' as a matter of policy." Although a child of good appetite, she made a gesture of pushing away food, saying "Take it away, I hate that stuff." And (quoting again) "Sometimes you will find her stark naked by her bed saying 'I don't know what to put on' and tossing her clothes about. If we say 'Put your vest on,' she replies 'I don't know what my vest is'."

My point, in summary, is that these samples of behaviour tend to interpret each other. Viewed together, they enable the clinician not only to diagnose an attitude, but to estimate its strength, its consistency, and the degree of its spread or projection over a range of situations—to what extent, in short, it becomes a dominant pattern of reaction. And above all, the clinician has an objective measure of the child's progress. Much of the behaviour just quoted belonged to the first few months of the child's stay in the institution. The fact that the gestures of rejection were gradually being discontinued meant that she was learning to accept the affection of the house mother and her staff, in other words the treatment was being successful.

A GUIDE TO OBSERVATION

It is now time to refer to the "Guide to Child Observation" which I have prepared. Its full title is "Guide to Child Observation (Children in Institutions, 5-15 years)" and the following is an extract, taken from the part of the section "Attitudes to Staff" which is most relevant to the behaviour of the five-year old girl quoted above.

Affection—Accepts and gives affection freely/always "coming for love"/demonstrative ("all over" people)/pretends indifference or independence/refuses affection avoids any intimacy.

Friendliness—Friendly, natural/unresponsive (cold, deep "you don't know how to take him"), cannot show appreciation ("takes things for granted").

Confidence—Talkative/quiet. Forward (opens conversation, tires people with constant chatter)/shy, aloof (does not make the first approach)/suspicious ("on the defensive").

This guide was evolved from a series of discussions which I held with house mothers and house fathers and their assistants—taking 20 children, spending an afternoon on each, and making notes upon the kind of things each child did, upon the way it behaved to the staff.

SUPPURATIVE PNEUMONIA *

HOWARD NICHOLSON

M.D. Lond., F.R.C.P.

ASSISTANT PHYSICIAN, UNIVERSITY COLLEGE HOSPITAL,
CHIEF MEDICAL ASSISTANT, BROMPTON HOSPITAL,
LONDON

*With illustrations on plate**(Concluded from p. 554)*

Non-specific Suppurative Pneumonia

In this lecture I wish to give an account of chronic non specific suppurative pneumonia. In describing the development of non specific suppurative pneumonia I have put forward the view that there is a whole range of aspiration pneumonias of varying severity in which suppuration occurs. One type when first observed presents as a solitary abscess cavity with little surrounding pneumonia, another as a predominantly pneumonic process in which large or small abscesses may develop. The importance of recognising the type which begins as a solitary abscess is that as long as it remains solitary and is not complicated by surrounding suppurative changes in the lung, it may sometimes be treated successfully by surgical drainage. Once it has become complicated and the disease consists no longer of a solitary abscess, then its progression cannot be distinguished clinically from that of the type which is mainly pneumonic from the beginning. What is more, their prognosis and treatment are the same, and I do not believe that it is useful to attempt their separation.

To this chronic phase of pulmonary suppuration many names have been applied—among others, a putrid abscess, necrosuppurative pneumonia, and spreading suppurative pneumonitis. It may simply and correctly be called chronic lung abscess, but this has the disadvantage that not all cases which may legitimately be included in the group have begun as abscesses, and in some cases abscesses may never have been recognised clinically or radiologically at any time. This, I am sure, leads in practice to confusion of thought rather than clarity, because when such cases are seen the observer frequently fails to regard them as examples of pulmonary suppuration, and he tends to place them in, and to think of them as, some quite separate disease entity, not amenable to the same lines of treatment.

Because of this, I think the term chronic non specific suppurative pneumonia is a useful one. The condition as it presents itself to the physician is characterised by the long standing production of purulent sputum which has a mixed and often varying flora, and in the lungs areas of pneumonic consolidation are found, often associated with abscess cavities. In fact, the name is simply a description of the disease as seen, and, as long as the user is clear that it is a comprehensive term and in no way separate from chronic lung abscess, it is a satisfactory one in practice.

INCIDENCE

Some idea of the incidence of chronic non specific suppurative pneumonia may be gathered from the numbers treated as inpatients at the Brompton Hospital. In 1946 there were 23 out of a total of nearly 1400 inpatients. It is perhaps easier to appreciate that 23 cases is quite an important group when it is made clear that the total number of non tuberculous cases treated in the same year was approximately 600. For the years 1947 and 1948 similar figures obtain, approximately 1 in 30 of patients in this hospital suffering from non tuberculous disease have chronic pulmonary suppuration of this type.

* The Goulstonian lectures for 1950 delivered at the Royal College of Physicians on Jan. 10 and 12.

The sex distribution shows a considerable preponderance of males over females. The number of patients of both sexes treated in the Brompton Hospital in three years is given in table I, which also shows the patients' age distribution. The disease is seen at all ages throughout adult life, but there is, in this group at any rate, a somewhat larger incidence in the fifth decade of life.

From this group of 57 cases, I selected 28 in which the course of the disease had been followed long enough to make possible a study of the clinical features of the disease. I propose also to compare certain of the clinical data of these 28 cases with those of a further 25 under

TABLE I—SEX DISTRIBUTION AND AGE INCIDENCE OF CHRONIC NON-SPECIFIC SUPPURATIVE PNEUMONIA AT THE BROMPTON HOSPITAL DURING 1946-48

Sex-distribution					
Year	No of cases				
	Men	Women			
1946	18	5			
1947	10	3			
1948	16	5			
Age incidence					
—	Age (years)				
	20-30	30-40	40-50	50-60	60-
No of patients	10	12	22	8	5

the care of Mr. Andrew Logan and myself in a military thoracic unit in the Middle East in 1941-45 (Logan and Nicholson 1949).

ETIOLOGY

In 19 of the 28 cases treated in the Brompton Hospital, it was possible to find a cause for the pulmonary suppuration.

Factors	No. of cases
Dental sepsis	7
Extraction of teeth	2
Operation under general anaesthesia	2
Chronic bronchitis	5
Others	3
None found	9
	28

Of the 7 patients with dental sepsis, 5 had gingivitis and 2 necrotic stumps. Of the 2 patients with a history of operation under general anaesthesia before the onset, I had been operated on for perforated gastric ulcer and the other had undergone thyroidectomy, in each case the patient had dental sepsis. In 1 patient the pulmonary suppuration followed the giving of thiopentone for a psychological investigation, in another it followed prolonged sea bathing, and in a third, who came from Poland after the war, it was perhaps related to poor nutrition. There was also a group of 5 cases in which the suppuration followed long standing bronchitis in which there was cough and the expectoration of small amounts of mucoid sputum. In the remaining 9 cases no aetiological factor was found.

ONSET

The great majority of the patients seen at the Brompton Hospital were not sent there until the disease had been present for some time, and it was seldom possible to get any clear idea of the mode of onset. All the Middle East group were in some form of military service and were accordingly sent to hospital early in the illness. Of the total of 25, all except 3 had radiographs taken early enough to demonstrate the original distribution of the lesions. In 5 of these patients the radiographs showed a cavity within three weeks of the onset, and in these patients the illness began acutely with cough, profuse

suggested above that bad human attitudes are by their nature habits of reaction, and the cure of a bad habit depends upon two things, insight into the habit and the wish to be cured. But the delinquent's bad attitudes are false attempts at adjustment, his way of mitigating his inner distress. He fears to face life and emotion in a normal way, because the pain of renewed failure would be more than he can bear. And so he clings to his antagonisms, his immorality, his cynicism and his attention filling diversions. Mere reason or mere insight will not avail against the bitterness of his life experiences.

The first task of the psychotherapist is to give him a new confidence in human relationships. Good human experiences must be provided which will counteract the previous bad ones. Of course the patient will resist, and distrust and test to the uttermost the sincerity of the friendship which is offered him. If furthermore it is offered carelessly, with too many blandishments, he will flee from it like a terrified animal. The drawing of a deeply withdrawn person into a fellowship group must be a carefully supervised process, and carried out by people who are aware of what they are doing. It is the psychologist's job to direct this process of recall to normal human feeling. Without this every other device of therapy is useless. No one would think of trying to revive a drowning man with his face still in the water.

It is apparent, also, that this approach to treatment presupposes an accurate diagnostic technique, not only to gauge the depth of the delinquent's false adjustment, but for the appraisal of his contemporary human situation. For example the therapist will have to judge whether his family life can be improved by the sympathetic intervention of an outsider, or whether it is emotionally so impossible that the patient must be transferred to an entirely new human environment. In any case, it is a question of tactics—a mutual improving of people's attitudes to each other, the removing of the barriers of pride which uphold antagonisms, the giving of insight and education in human relations in doses that can be absorbed. This is quite another thing from the mechanical weekly clinical interview which is sometimes called treatment. None of the clinicians to whom I have known approved school boys referred have ever asked for consultations with the staff as to the boys' person attitudes, nor, astonishingly enough, have they thought of seeking information as to their family situation. The treatment was an isolated weekly occurrence, to be weighed against the occurrences of every other hour of the week which the clinician ignored. The influence of that one hour, in terms of happy human experience, is of particularly little consequence with the type of delinquent who has a knack of creating bad situations against himself.

A NEW TYPE OF SOCIAL PRACTITIONER?

There is a further consideration regarding our psychological services—the kind of treatment which our new emphasis upon human relations involves makes one wonder if the present division of labour between psychiatrist, social worker, educational psychologist, and psychiatrist is a fruitful one. Can a written or even a verbal report of any reasonable length communicate from the one to the other the detailed evidence of what is wrong with a human situation? At any rate, to be adequate it must involve an enormous amount of time and drudgery, and a second hand report lacks the vividness of personal and sometimes incommunicable experience. I feel that a new type of social practitioner must be developed, with the individual responsibility for a case like that of the general medical practitioner, who sees what is wrong and acts upon it himself.

One of the defects of our present clinical service is that there is no responsibility for success or failure. No one seems to mind if the treatment fails, perhaps

no one expects it to succeed. It is well for us that no modern Molière is at hand. The present tendency to flee competition and the test of results is a neurotic one. If the medical practitioner is not afraid to let his reputation hang upon his devotion to his work and upon his successes, why should not his brother the psychotherapist accept a similar challenge?

Finally, it is apparent that case investigation of the type outlined is patient, time consuming work, to be carried out by specially trained people. The evidence of emotional ill health is perhaps more elusive than that of physical disease, and so the investigation and treatment of each case will on the average be more expensive. Can society afford it? Let us review the debit and credit items on the balance sheet. On the one side there may be, say, a whole month of a professional person's time, on the other the expense of a whole delinquent, neurotic, or psychotic lifetime on public charge. Say £60 against many thousands. It seems a fairly safe investment. In physical medicine no one queries the necessary expense of a long case, we recognise, at least in principle, that physical suffering and human life are above mere financial considerations. Why should we then begrudge the expense when a lifetime's happiness, and perhaps the happiness of succeeding generations, is at stake? But before we press these points we must convince the public that the psychologist can deliver the goods. It is no use, for example, asking the school to spot the unsettled child at an early stage unless there exist the competent family advisers to deal with the case effectively.

CONCLUSION

It may be felt that I have not spoken as specifically about the study of delinquency as I might have done. But persistent delinquency in its irrational, undeterrable, breakdown stage can be defined as a neurosis of a type which gives some point to lawbreaking. Essentially the same types of reaction are, I believe, to be found in not formally delinquent neurosis. The study of the one is largely the study of the other, and the same exact methods of observation are needed for both.

To many psychologists my remarks will sound too sweeping. What can happen in one clinic would be impossible in another. It is no new doctrine, in the progressive clinic, that therapy must be directed not only upon the difficult child but upon his family. And I am but one of a number of psychologists who are trying to think things out afresh in terms of human relations. It is owing to the youth of our science that it still suffers from ideas and methods which have been borrowed from physical medicine. In dragging the inadequacies of our old fashioned brethren into the limelight my intention has been mainly to show to what extent this new approach requires an overhauling of psychological practice and different types of professional training.

“Benefits in the form of a service have thus further characteristic that the rights of the citizen cannot be precisely defined. The qualitative element is too great. A modicum of legally enforceable rights may be granted, but what matters to the citizen is the superstructure of legitimate expectations. It may be fairly easy to enable every child below a certain age to spend the required number of hours in school. It is much harder to satisfy the legitimate expectation that the education should be given by trained teachers in classes of moderate size. It may be possible for every citizen who wishes it to be registered with a doctor. It is much harder to ensure that his ailments will be properly cared for. And so we find that legislation, instead of being the decisive step that puts policy into immediate effect, acquires more and more the character of a declaration of policy that it is hoped to put into effect some day.”—Prof T. H. MARSHALL, *Citizenship & Social Class*, Cambridge, 1950, p. 58.

Fig 22—Photograph of cut surface of left upper lobe showing extensive consolidation and cavitation

this extension was not hindered by the interlobar septa. Besides this method of spread, there were a number of instances—7 in each of the series I have studied—where spread occurred to parts of the same lobe or lung which were not contiguous. In these circumstances it is, I think, reasonable to assume that the spread took place by aspiration of material from the affected part of the lung into the bronchi of fresh segments. In addition, there was 1 example in the military hospital group, and 2 in the Brompton Hospital series, of spread to the other side.

Cavitation may take place at any stage of the disease, it may develop early or late in the original lesion, and may sometimes disappear. The freshly invaded parts frequently cavitate, and it is not uncommon to have multiple cavities of varying size in the same lobe or lung. In the series studied the radiological appearance often remained stationary for two to three months, and this was commonly associated with clinical improvement. Sooner or later there was usually recrudescence of the symptoms, associated with radiological evidence of further spread of the disease.

In most cases there was at some time evidence of at any rate partial clearing of the pneumonic process. Where this happened, the lung showed radiological evidence of fibrosis. In the military hospital group there were 2, and in the Brompton Hospital series 7, cases in which the radiographs, after recurrent episodes of consolidation and cavitation, showed only evidence of fibrosis and distortion of the lung. This is a stage to which the term "burnt-out" is sometimes applied, the implication being that the danger is over. I am sure that this is not so, it is not uncommon to see the disease light up again in these cases with recrudescence of the inflammatory process in the fibrotic area and spread to previously unaffected parts. When bronchograms are done in this stage of fibrosis they show distortion of the bronchial tree and bronchiectasis, which may be of any type. Bronchograms are of no value in the active phases of

Fig 23—Photomicrograph of part of wall of central cavity of specimen shown in fig 22; its partial covering of epithelium can be seen

the disease because the iodised oil rarely enters the affected parts of the lung, the associated bronchi being then occluded by pus and pulmonary debris. Such importance as they have is in relation to the more quiet phases of the condition when the pulmonary changes are principally those of fibrosis, and then their main use is in deciding on treatment. I shall, therefore, refer to bronchography again when I come to treatment.

EMPHYEMA

In one of the military hospital cases, and also in one of the Brompton Hospital group, empyema developed. In both instances this happened quite late in the course of the disease—namely, one year and four years after the onset of the pulmonary suppuration. In both these cases the empyema occurred in a part of the pleural cavity remote from the original site of the disease. The development of the empyema was related to the spread of infection to a fresh area of the lung, where presumably the pleural layers had not previously been inflamed and were not adherent. In one there was a bronchial fistula

Fig 24—Photomicrograph of part of consolidated lung shown in fig 22. Fibrous tissue, collections of inflammatory cells and alveolar areas lined with cubical cells can be seen. In upper part of photograph two groups of lipoid filled macrophages are shown

into the empyema, but in the other no fistula was evident. Both cases were treated by drainage and they healed, the progress of the pulmonary suppuration was not affected.

PATHOLOGICAL CHANGES

In 12 of the military hospital cases and in 13 of those treated at the Brompton Hospital, the diseased lung tissue was examined either post mortem or after its surgical resection. The naked eye and microscopic features were the same in all cases, and were the same as those described in chronic lung abscess. The pleura covering the affected lung was thick and widely adherent to the wall of the thoracic cavity. The interlobar fissures were obliterated. The lung itself was mostly airless, but there were areas of emphysema. Abscess cavities of various sizes, often multiple, were seen in most of the specimens. Not uncommonly the cavities apparently extended across segmental boundaries. In some specimens dilated and distorted bronchi ringed with fibrous tissue were visible.

On histological examination the tissue showed a variety of appearances. The cavities were lined with granulation tissue, showing more or less advanced fibrosis and infiltration with plasma cells and lymphocytes. In some there was a partial lining of columnar or squamous epithelium. The alveoli surrounding these abscess cavities were filled with exudate, which in some places was undergoing organisation and fibrosis. Groups of alveoli lined with cubical cells were seen, and there were

sputum, and pain in the chest—the onset typical of an acute solitary lung abscess. There were 10 further cases in which the onset was acute with similar symptoms, but in which the lesion seemed to be pulmonary consolidation, and cavitation was not seen in the first three weeks. In the remaining 7 cases the onset was more gradual, consisting usually of cough and increasing fever, and evidence of pulmonary consolidation was found radiologically.

In all cases there was an initial febrile period which did not usually persist for more than a few weeks. Purulent sputum was coughed up from the onset in all cases in this group except 1, in which for the first four months only traces of mucopus were expectorated. In 13 instances in this group the sputum was described as offensive or foetid at the onset.

CLINICAL COURSE

Clinically, the progress of the disease was similar in the two groups of cases. The fever at the onset settled, but was followed by repeated febrile periods, lasting usually a week or two, and often associated with a reduction in sputum, in these episodes the temperature would reach 101°F or, rather infrequently, higher levels. Then, often after sudden expectoration of profuse sputum, or more gradual increase in its amount, the temperature would fall to normal. Between these attacks most patients in both groups were able to be up and about and often felt very well. In this connection it is interesting that of the 28 patients treated in the Brompton Hospital, no fewer than 12 had been ill for more than twelve months before being sent to the hospital. There is no doubt that the periods of relative well being are dangerous to the patient, obscuring the fact that he still suffers from a serious disease.

In all cases, throughout the course of the disease cough was present and produced purulent sputum in amounts commonly between 2 oz and 7 oz daily. The amount of sputum brought up each day was in some cases very large. One of those seen in the Brompton Hospital had 30 oz of sputum a day, and one of the Middle East patients brought up almost 2 pints of foul-smelling pus each day for four or five weeks. Fœtor of the sputum may come and go during the illness. In only 4 of the Middle East cases was the sputum non foetid throughout the period of observation, which ranged from three to twenty one months, with an average of ten months. Of the Brompton Hospital group, 11 had non foetid sputum during their stay in hospital, which averaged just over three months. With longer observation the number might well have been smaller.

Hæmoptysis was observed quite often in both groups of patients. It was noted at the onset by 9 of the Brompton Hospital patients and by 3 of the other group as streaking of the sputum. In the majority, blood streaked sputum was expectorated occasionally during the illness, and 4 patients had more substantial and repeated hæmoptyses, of which the largest seen amounted to 1 pint.

Clubbing of the fingers was seen in a very high proportion, but not in all. There were 2 patients in the military hospital group and 4 in the Brompton Hospital series who were not thought to have clubbing. Of the 23 patients in the military hospital group who showed finger clubbing, 1 also had hypertrophic pulmonary osteo arthropathy.

On physical examination of the chest, signs of pulmonary consolidation were present at some time in most of the cases, but these were seldom as gross as might have been expected from the radiological appearances, and they varied considerably during the disease.

White-cell counts were carried out frequently in both series of patients. It was unusual for these to be much

raised. Counts of 10,000–12,000 per c mm were commonly seen, on only three occasions were counts of more than 20,000 per c mm recorded. In all cases the differential count showed approximately normal percentages.

Examination of the sputum was repeated many times in all these cases. In each, at least twelve sputum specimens were examined for tubercle bacilli and found to be negative. Also, at least one specimen was cultured for tubercle bacilli, and in no case was the bacillus grown. There is undoubtedly, however, an association between chronic non specific suppurative pneumonia and pulmonary tuberculosis, which I shall discuss later. In each case examination for other organisms showed a mixed flora. I have already referred to the difficulty of establishing exact bacteriological diagnosis in these cases, and during the period over which they were observed the flora was found not only to be mixed but to vary from one week to the next. The organisms most commonly found were of the following types: *Streptococcus viridans*, hæmolytic streptococcus, non hæmolytic streptococcus, pharyngeal neisseria, *Staphylococcus aureus*, pneumococcus, organisms of the hæmophilus group, occasionally diphtheroids, and occasionally Friedländer's bacillus (*Bacterium pneumoniae*). It was never possible to relate the organisms found to the severity or course of the infective process.

Bronchoscopic examination of these patients under local anaesthesia is of great value, and in the two groups of patients which I am describing this was only rarely omitted—either because the patient was regarded as too ill, or because he was incapable of adequate coöperation. The information obtained was, first of all, of the absence of obstruction of the major bronchi, to the importance of which I shall refer again in discussing differential diagnosis, and, secondly, of the presence of redness and oedema of the mucous membrane of the bronchi associated with the affected areas, thus assisting in defining the position, and often the extent, of the affected part of the lung. Further, it was often possible to aspirate for examination some of the pus welling out of the affected bronchi. The advantage of examining this material for tubercle bacilli and other organisms before it is contaminated in the mouth is considerable, and more exact bacteriological information may eventually be obtained in this way.

RADIOLOGICAL FINDINGS

It is possible to follow the course of this disease only by repeated radiographs. From a study of those taken in the two series of cases from which I am drawing my data, I shall try to describe the more common ways in which the radiological appearances develop and progress. I have previously, in describing the onset of this condition, pointed out that 5 of the military hospital cases were characterised by the early formation of an abscess cavity and were at this stage undoubtedly examples of typical solitary abscess. Beginning in this way, the abscesses tend to occur most frequently in the posterior and axillary parts of the posterolateral segments of the upper lobes. A large proportion of these cases do not, however, show cavitation at the onset, but consolidation only. This is often segmental, but is not always confined to a single bronchopulmonary segment. Thus, in 22 cases in the military hospital group there was radiological evidence of the early distribution of the lesions. Of these, 7 showed involvement of a whole lobe and 1 of the whole of one lung, and in 2 there were pneumonic areas scattered throughout a lobe. However, in the remaining 12 cases the lesion was clearly segmental at the onset, whether or not the consolidation broke down early to form an abscess.

The subsequent radiological appearances were varied. The course most usually followed was that the disease spread apparently directly into the surrounding lung,

DR NICHOLSON SUPPURATIVE PNEUMONIA

occasional abscess like masses of polymorphs. Groups of fat containing cells filling alveolar spaces were common, and presented an appearance like that seen in lipoid pneumonia. The bronchi were frequently distorted and dilated, and in some instances were distended and formed the walls of cavities. The walls of the bronchi in the affected parts of the specimens showed at some points complete necrosis, at others inflammatory infiltration, and at others fibrosis. Some of the features described in this section are shown in figs 22-24.

ILLUSTRATIVE CASES

Before going on to consider the differential diagnosis and treatment, I should like to describe three cases by way of illustration.

The first example (case 2 of Logan and Nicholson (1949)) shows the effect of long continued suppuration in the lung.

Case 9—A Libyan Arab, aged 20, was admitted to hospital in June, 1942. Five months before, he had become ill with fever, cough, and sputum.

On admission, his general condition was fairly good, he was febrile to 101°F, and was coughing up 10 oz of foetid purulent sputum each day. His fingers were clubbed. Radiographic examination (fig 25) showed a cavity in the right upper lobe, surrounded by consolidation and fibrosis, the transverse fissure being displaced upwards. Sputum examination showed the presence of a mixed flora with pneumococci predominating. Bronchoscopy, carried out shortly after his admission, showed the right main bronchus to be oedematous, with pus exuding from the upper lobe bronchus.

For a month the patient improved clinically and his sputum diminished. Then he had an exacerbation, and sulphapyridine, 1 g every four hours, was begun. He suffered no ill effects, and the chemotherapy was kept up for eighteen days. At the end of this long course he was greatly improved and had only 3 oz of sputum each day. The clinical improvement was maintained, but radiographs six months after admission (fig 26) showed that although the upper lobe changes were mainly of fibrosis, there was a large pneumonic area in the right lower lobe. Two months after this the patient developed a right basal empyema. At this time the lower lobe contained a cavity with a fluid level and much surrounding consolidation. The empyema was drained and healed.

After this the patient steadily improved. The radiographic appearance of his chest a year after admission is shown in fig 27, there is considerable fibrosis throughout the right lung. He was then well and free from cough and sputum. Bronchograms (figs 28 and 29) showed a distorted right bronchial tree with irregular cavities in communication with the bronchi of all lobes.

The second example is of less extensive disease without definite abscess formation and with a fairly satisfactory result after treatment.

Case 10—A carpenter, aged 43, was admitted to the Brompton Hospital in September, 1940. For twenty years he had had a cough with a little mucoid sputum, and had been regarded as having chronic bronchitis. About three months before admission he had been taken ill with a pain in the right side of the chest, fever, and increased cough. After eight or nine days, his sputum had increased, and had become purulent and streaked with blood.

When admitted to hospital, he was febrile to 99°F and was coughing up 3-4 oz of purulent, non foetid sputum. His fingers were clubbed, but abnormal physical signs were not detected on examination of his chest. The radiographs (figs 30 and 31) showed consolidation, mainly in the posterolateral segment of the right upper lobe. Sputum examination showed a mixed flora, and *Strept. viridans*, micrococci, and a few colonies of hemolytic streptococci were grown. Bronchoscopy revealed nothing abnormal apart from mild inflammatory changes at the right upper lobe orifice. He was treated with postural coughing, and penicillin by intramuscular injection, clinically his condition improved, with reduction of sputum to less than 1/2 oz each day. The radiographic shadow diminished, but did not clear up completely.

Fig 34—(Case 11) Anteroposterior radiograph of right knee showing subperiosteal new bone

He left hospital after a little more than a month, and in the next six months he had two exacerbations, with increase in sputum and in the pneumonic area in his right upper lobe. A radiograph (fig 32) taken three months after his discharge from hospital shows the appearance of the lung in one of these exacerbations. After this his cough and sputum diminished steadily, and radiographs of his chest showed mainly linear shadows, attributed to fibrosis in the right upper lobe. A radiograph taken more than two years after his discharge is shown in fig 33.

In the third case lobectomy was carried out.

Case 11—The patient was a Greek soldier, aged 37, who was admitted to hospital in September, 1942. Ten months before, he had developed fever, cough, and profuse sputum, and a diagnosis of lung abscess had been made.

On admission, he was in good general condition and afebrile, but with a cough and 2 oz of purulent, non foetid sputum each day. His greatest complaint was of pain in the knees and wrists. His fingers were clubbed, but abnormal physical signs were not detected in his chest. He had several septic roots in his upper jaw and his oral hygiene was poor. Radiographs of his wrists, ankles, and knees showed subperiosteal thickening, that of his right knee (fig 34) demonstrates this new bone formation. Radiographs of his chest (figs 35 and 36) showed consolidation in the left lower lobe, with more

than one cavity. Bronchoscopy showed a normal bronchial tree, apart from the presence of pus in the left lower bronchus.

A few days after admission, two roots were removed, under local anaesthesia, from his upper jaw. Next day the patient had a rigor and became febrile to 103°F. His sputum increased and he became very ill, with a rigor every second day. This continued and was unaffected by a course of a sulphonamide. Other causes for his fever having been excluded, an attempt was made to drain the main pulmonary abscess. Rib resection was carried out, but free pleura was opened. A firm lump, 2½ in in diameter, was found in the left lower lobe, with a narrow area of loosely adherent pleura over it. It was not thought justifiable to carry out the drainage, and the pleural cavity was closed. Over the two months after this operation, the fever gradually settled and the patient's general condition improved. The radiological appearance at the end of this time remained essentially unchanged. Fourteen months after the onset of the disease, a left lower lobectomy was carried out and was followed by complete relief of symptoms.

DIFFERENTIAL DIAGNOSIS

In describing some of the specific pneumonias which are associated with cavity formation in the lung and with suppuration, I have indicated how they are distinguished from non specific suppurative pneumonia. The cavitation which occurs during pneumococcal pneumonia is transient and apparently followed by healing. Recognition of the chronic pneumonia due to Friedländer's bacillus may be more difficult, the course and radiological appearance may be very similar to non specific chronic suppurative pneumonia, and the distinction depends on the recovery from the sputum of *Bact. pneumoniae* in pure or almost pure culture. In staphylococcal pneumonia, the clinical features, particularly at or near the onset, may strongly suggest the cause. The staphylococcus may be found in pure culture in the sputum or may be recovered from the blood stream. In the more chronic phase of the illness the bacteria recovered from the sputum may be varied, other organisms besides the staphylococcus having established themselves in the damaged lung. In these circumstances it may be possible to guess the original nature of the infection from the clinical course of the disease, but in general the distinction from the non specific variety of pulmonary suppuration is not then very valuable, since the outlook and treatment of both are the same. The recognition of the infection of the lung also depends on the type of the organism.

Pulmonary tuberculosis might be expected to be commonly confused with suppurative pneumonia. Certainly the long course of both and the similar radiological appearance may give rise to difficulties in diagnosis. Nevertheless I believe it is usually possible to make the distinction. In the first place, there is the association of pulmonary suppuration with sources of infected material in the respiratory tract. Then, the onset with the production of a considerable, and sometimes very large, amount of sputum fairly early in the disease is characteristic of suppurative pneumonia. This is quite unlike the early stages of pulmonary tuberculosis, in which it is

rare for large quantities of sputum to be produced. Finally, repeated examination of the sputum for tubercle bacilli with negative results, both from direct examination and from culture, may be regarded as adequately distinguishing suppurative pneumonia from tuberculosis.

There is, however, a group of cases, of which I propose to describe an example, in which the two diseases occur together.

Case 12.—A man, aged 51, was admitted to the Brompton Hospital in October, 1947. He had been regarded as having chronic bronchitis since the end of the 1914-18 war, and since then had had some purulent sputum. Six months before admission, he became ill with fever and malaise. After three or four days of this illness he, as he said, "smelt fumes in his mouth" when lying on his left side. There was no great increase in his cough or sputum, but after this the sputum did occasionally become offensive. A month before admission he noticed streaks of blood in the sputum, and he was seen at his local tuberculosis clinic, where his sputum was repeatedly examined and found free from tubercle bacilli.

On admission to the Brompton Hospital, he was febrile to 100°F, he had some cough, and was bringing up 2 oz. of purulent, but not fetid, sputum each day. His fingers were clubbed, and he had physical signs suggesting consolidation over the upper part of his right chest posteriorly. The radiological appearance, shown in figs 37 and 38, did not change much during his stay in hospital. It will be seen that there is consolidation in the right upper zone with probably irregular cavitation in it. The lateral view shows that a large part of the upper lobe is consolidated.

Examination by smear and concentration of eight successive specimens of sputum again failed to demonstrate the tubercle bacillus. The sputum contained a mixed flora, and on one occasion only *Bact. pneumoniae* was isolated from it. Bronchoscopy revealed no abnormality in the bronchial tree. A trap specimen of secretion aspirated at bronchoscopy from the upper lobe bronchus did not contain tubercle bacilli. A course of penicillin and sulphamezathine was given, and this was followed by reduction in the amount of sputum and gradual clinical improvement. Then, two days after the bronchoscopy, a few tubercle bacilli were found in his sputum, and successive daily specimens after this showed the organisms to be present in increasing numbers.

The patient died at home nine months after the onset of a coronary thrombosis. Necropsy is reported to have shown extensive fibrocaseous tuberculosis of the right upper

It is difficult to believe that this was simply a case of pulmonary tuberculosis from the beginning. It is so far more likely that suppurative pneumonia developed in a pulmonary segment that was already the site of a healed or quiescent tuberculous lesion. The destructive suppurative process involved the possibly encapsulated tuberculous focus, and allowed its still living bacilli to invade the partly destroyed lung.

I have already drawn attention to the relation of bronchial carcinoma to pulmonary suppuration, and in practice the distinction between suppuration associated with carcinoma on the one hand, and non specific suppurative pneumonia on the other, may be extremely difficult. For example

Case 13.—A Norwegian seaman, aged 52, was admitted to hospital in January, 1949. He had been ill for two months with a cough and an ounce or two each day of mucopurulent sputum never fetid. He had lost 10 lb in weight. A radio-graph (fig 39) taken shortly before admission showed consolidation in the left mid zone. Lateral views showed the consolidation to be in the apical segment of the left lower lobe, and this was confirmed by lateral tomograms (fig 40). Bronchoscopy showed pus exuding from the orifice of the bronchus to this segment, the orifice itself was inflamed but no growth was seen. A biopsy specimen taken from it showed no evidence of growth. The patient was treated by postural coughing and by penicillin and sulphamezathine. As a result of this, his sputum diminished in amount but no striking change took place in the radiological appearance.

A month after the patient's admission, in view of the lack of radiological change and in the belief that he had a carcinoma probably of the bronchus to the apical segment of his lower lobe beyond the range of bronchoscopic vision it was decided

DR NICHOLSON SUPPURATIVE PNEUMONIA

DR STOKER Q FEVER IN GREAT BRITAIN

It is possible, I think, to summarise from these results a reasonable programme of treatment. When the patient first comes under care in hospital his sputum should be examined and cultured and the sensitivity of its organisms to antibiotics and the sulphonamides determined. Meanwhile, an intensive course of postural drainage and coughing under the care of a physiotherapist should be begun. In almost all cases the sputum contains large numbers of organisms sensitive to penicillin, and penicillin should be given in doses of the order of 1 million units per day. I think it is valuable at the beginning of such a course to give sulphamezathine in the usual dosage for six or seven days. On such treatment as this, the patient in the matter of a few days feels very much better and his sputum begins to decrease, and, if this was offensive at the beginning, the fetor will cease to be noticeable. It may be worth while after perhaps two weeks, if the sputum persists, to re-examine its flora, since it may now contain organisms which are mainly penicillin resistant, and one of the other antibiotics may be useful. In the majority of cases by such measures as these it is possible to achieve a state in which there is very little—but usually still purulent—sputum, a feeling of well being, and radiographic evidence of fibrosis where there had previously been consolidation and cavitation.

This must be regarded as an adequate result in some patients—that is to say, those who, by reason of extensive and perhaps bilateral disease, or of old age, or of other related or unrelated diseases, are unsuitable for thoracotomy and pulmonary resection. Many of these patients will have further episodes of pulmonary infection, and arrangements should be made to admit them to hospital for further treatment by postural drainage and chemotherapy during each recurrence.

In those patients where no such contra-indications are apparent, the next step should be to carry out bronchography in order to determine the extent of the severely damaged lung—that is to say, which lobe or lobes are involved and which are apparently intact. Where the extent of the damage, as shown by bronchograms, does not preclude it, the affected lobe or lung must be resected. This is the only measure likely to restore the patient to health and to stop the progression of the disease.

Summary

Certain specific pneumonias associated with suppuration are described.

The relation of bronchial carcinoma to pulmonary suppuration is discussed.

Patients with suppurative pneumonia not due to a specific organism or to bronchial carcinoma have in the sputum a mixed bacterial flora, the members of which are not specifically invasive for the lungs. These cases are held to be localised aspiration pneumonias, and form a series ranging from those in which the suppurative changes are slight to those which present as acute solitary lung abscess.

Cases of non-specific suppurative pneumonia may progress chronically, and their course is similar whether they begin as solitary abscesses or as predominantly pneumonic lesions.

In chronic non-specific suppurative pneumonia, once considerable suppurative changes have occurred, resection of the affected lobe or lung is the only measure likely to restore the patient to health.

I wish to thank the members of the Brompton Hospital staff for allowing me to use the hospital records—in particular I am grateful to Dr Clifford Hovle, Dr J G Scadding and Dr A. Foster Carter, who allowed me to make reference to cases under their care and gave me much other assistance. I also owe thanks to Prof M L Rosenheim who allowed me to use the records of a case under his care at University College Hospital and to Mr Andrew Logan for his help and cooperation over many years.

EVIDENCE that some of the cases of atypical pneumonia occurring in Great Britain were due to *Rickettsia burnetii* was provided when 3 of 24 patients with this syndrome were found to have complement fixing antibodies to this rickettsia (Stoker 1949). Titres in 2 of the cases were high and followed an illness clinically suggesting Q fever, while the titre in the third case was lower and was more probably related to past infection than to the recent attack of pneumonia. One of the patients had never been abroad and it seemed certain that he had acquired his infection in this country.

The final proof of the presence of Q fever in Great Britain was the isolation of the causal rickettsia, *R. burnetii*, from the blood of a patient with atypical pneumonia during a small outbreak at the Royal Cancer Hospital London. The clinical aspects of Q fever in this outbreak were described by Harman (1949) and the bacteriology by MacCallum et al (1949).

Since the outbreak at the Cancer Hospital sporadic cases of Q fever have been found in Kent, Devon,

that his chest should be explored. Left thoracotomy was performed, and a hard mass was found in this segment, densely adherent to the chest wall. Pneumonectomy was carried out, and the patient recovered and returned to Norway. On examination of the specimen, no evidence of carcinoma was found, but the apical segment of the lower lobe was occupied by a chronic suppurative process.

Obviously, when on bronchoscopy a biopsy specimen containing carcinomatous tissue can be obtained, diagnosis is not difficult. At the other extreme, when cases of extensive pulmonary suppuration show considerable radiological shrinkage of the lesion as well as clinical improvement on treatment by postural coughing and chemotherapeutic agents, they may be cautiously regarded as not being associated with bronchogenic carcinoma. Even this is by no means certain and must be checked by repeated bronchoscopy. When the lesion is of lobar distribution more weight can be given to a negative bronchoscopy, since an associated growth would almost certainly have involved the main lobar bronchus and should therefore be visible bronchoscopically. With lesions of segmental distribution a negative bronchoscopy is not so significant, since the segmental bronchus can be involved by a carcinoma which may be beyond bronchoscopic vision. It is this sort of lesion which gives the greatest difficulty in differential diagnosis. In the active phase of the disease no important information is to be obtained from bronchography, since even where there is no carcinomatous obstruction the iodised oil usually fails to enter the relevant bronchus. I am sure that in cases of doubt, if other considerations allow it, thoracotomy should be performed.

The only other condition to which I am going to refer is bronchiectasis. It is possible that bronchiectasis complicated by consolidation of the lung around dilated and inflamed bronchi may be confused sometimes with chronic suppurative pneumonia. The history will usually suggest the correct diagnosis. The bronchiectatic patient will commonly have a long history, very frequently going back into childhood, of cough and sputum. He will have had pneumonic episodes in the past, and the pneumonia with which he presents himself will usually run its course very rapidly. However, pulmonary suppuration may be associated with bronchiectasis and arise by the infection of infected material from the dilated bronchi in other parts of the lung.

TREATMENT

In both the groups of cases to which I have been referring, the first method of treatment adopted when the patient was admitted to hospital was postural drainage under the care of a physiotherapist. Both groups were given courses, in some cases repeated, of one or other of the sulphonamides. Of the military hospital series, only 8 were given penicillin, and even in these cases the doses given were small by present day standards, since the drug was difficult to obtain in the Middle East in 1944 and 1945. In the Brompton Hospital group penicillin was administered in much larger dosage and for longer periods. The results in patients treated by such measures as these are summarised in table II. In the military hospital group, 1 patient became free from symptoms, and the radiograph of his chest showed only slight fibrosis. Another patient became well with an apparently normal radiograph, but had 1 oz of purulent sputum each day. In the Brompton Hospital group, following these measures, 3 patients became free from symptoms and had relatively slight fibrotic changes to be seen radiologically in their lungs.

Both series included patients who were greatly improved clinically and had much less sputum than before treatment, but in whom radiological changes indicated severe fibrosis. In the military hospital series there were 2 such cases, and in the Brompton Hospital series, 7. Bronchograms of patients with gross fibrotic changes showed

13 of the Brompton Hospital group, and 10 of the military hospital group were treated surgically.

distorted and dilated bronchi in the diseased area and it is hard to believe that the outlook for such patients is other than bad, in view of the danger of reinfection of the damaged lung and further progression of the disease.

In the series of patients treated at the Brompton Hospital, there were 4 who, after postural drainage and chemotherapy, remained essentially unchanged with progressive disease. Of the other series, 9 continued over the period for which they were observed to be ill with extending inflammatory changes in their lungs. There were also 2 patients in the military hospital series who died, 1 from cerebral abscess and 1 from overwhelming infection. In the Brompton Hospital group 1 patient died from spread of his pneumonic process.

The most obvious difference between these results in the two series is that fewer of the Brompton Hospital than of the military hospital patients were left with progressing disease, and more had symptomatic improvement, though with residual fibrosis. There can be little doubt that this difference is due to the use of penicillin in the Brompton Hospital cases. What effect penicillin is likely to have on long term prognosis in these chronic cases is difficult to assess at present, since it has been used in adequate dosage for so short a period.

In each group surgical resection of the diseased lobe or lung was carried out in a number of cases. In the Brompton Hospital series lobectomy was carried out in 10 cases and pneumonectomy in 3. In all but 2 cases these procedures were followed by satisfactory results, the patient having either no symptoms or no more than the expectoration of a trace of mucoid sputum with no evidence of remaining pulmonary suppuration. In 1 of the 2 unsuccessful cases the remaining lobe is the site of further suppuration, and in the other the patient died during the operation. In the military hospital group lobectomy was carried out in 9 cases and pneumonectomy in 1. Satisfactory results were obtained in 6 cases, and there were 4 deaths.

In observing these results of treatment it has seemed to me that the main advantage—a very great one—which has accrued from the introduction of penicillin is that its use reduces the amount of the patient's sputum and improves his general condition, thus increasing the safety of resection of the diseased pulmonary tissue. The main danger in the use of penicillin may well be that it reduces symptoms while leaving extensive fibrotic and destructive changes in the lungs. In some cases, where pulmonary resection is precluded by the extent of the disease or other considerations, the reduction of symptoms is wholly beneficial, but in others it may give doctor and patient a quite unjustified sense of security and thus prevent or delay the necessary operation.

Other methods of treatment were used. In the military hospital series external drainage of cavities was carried out in 6 cases. In no case did this procedure benefit the patient, and the suppurative disease continued to spread in the lung. In 1 case in each series a thoracoplasty was carried out, without benefit in either instance.

Fig. 1.—Time relation of illness of case 5 to onset of illness in cases 1-4

found in Q fever. This information was not available at the time, but investigations proceeded on the hypothesis that case 5 had had Q fever and that either he had been admitted to hospital during the incubation period of the disease, having been infected shortly before admission, or that he had been infected very shortly after admission. The period of eighteen days between admission and the onset of his illness was consistent with either possibility.

These alternatives of infection outside or inside the hospital were investigated concurrently, the first by a visit to case 5's home in Kent, the second by a search for any previous cases of Q fever among the patients in X ward or the staff of the hospital in general.

Of the 31 patients who had been in X ward at the same time as case 5, none had had a suspicious fever before the onset of his illness, and only 6 had had any fever between May 27 and June 24, when case 5 had been in the ward. In 2 patients the fever had clearly been related to a recent operation, and in the other 4 probably to their cancerous condition. Sera taken three or four months later from 5 of the patients who had been febrile were negative for *R. burneti* antibodies, the sixth patient had died shortly after discharge from hospital. All the 31 patients were followed up, and none had had any unexplained febrile illness after discharge from hospital. An attempt was made to examine the serum of each patient, and this was done with negative results in 22 patients, but in 5 cases blood could not be obtained owing to death since discharge, and 4 patients refused venepuncture.

The staff of X ward, other than case 2, consisted of a house physician, a sister, eight nurses, two ward orderlies, and two maids. None of these persons had been ill and all, except the house physician and the maids, who refused specimens, were serologically negative. There was no other illness clinically or serologically suggesting Q fever in the general staff of the hospital at this time, and no record of the importation of any likely source of Q fever, such as raw milk, raw dairy foods, and animal products was found on inquiry at the hospital catering department.

It therefore seemed that case 5 had been admitted while incubating Q fever. It was also established that he had not been exposed to any suspicious case or possible source of Q fever during the journey on May 27 from his home in Kent to the Royal Cancer Hospital. The ambulance crew who had been with him on this journey were well and serologically negative.

EPIDEMIOLOGICAL STUDIES IN KENT

Early in September a visit was made to case 5's household, which consisted of his wife and two daughters, in a seaside town of NE Kent. Another married daughter and two married sons were occasional visitors. The three daughters and one son were quite well and their

sera were negative. The other son was also well, but he lived in another part of the country, and his serum was not examined. Case 5's wife (case 6), however, was confined to bed with a vague illness complicated by cardiac failure, and her serum had a high titre of *R. burneti* antibodies (1/640). Her illness had started with diarrhoea on July 25, and a minor stroke followed on Aug 1. The clinical picture was not that of Q fever, and it was uncertain whether the *R. burneti* antibodies resulted from the illness or past exposure. She had not visited or seen her husband since he went to hospital or after his death, but had received letters from him.

Case 5 had been a jobbing tailor by trade but of recent years had only done work for neighbours and friends. He had neither history of occupational exposure to animals, as is found in some cases of Q fever, nor had he repaired any clothing soiled with animal excreta, handled packing straw, or recently received food parcels from abroad. There was a small retail dairy A about 100 yards from his house, and a butcher's shop with a sausage manufacturing plant at the back of the premises.

The investigations of Huebner et al (1948) in California showed that raw milk from many dairy herds was infected with *R. burneti*. So, since no other source of infection had been found to explain case 5's illness, his milk-supply was investigated. His household was supplied by the small retail dairy A which received bulked heat-treated milk from London and some raw milk from local farms. These two milks were bottled at the dairy and sold separately, and it was impossible to find out which customers had raw and which had pasteurised milk, if, indeed, distribution was at all consistent. Dairy A and two other local dairies B and C, one (B) combined with a farm and both unconnected with case 5's household, were investigated. Volunteers were bled, and their sera were tested for *R. burneti* antibodies. At dairy A, 2 of the 8 volunteers had low titres of complement-fixing antibodies to *R. burneti*, and 6 of the 19 volunteers from dairies B and C were positive, 2 having titres of 1/80 (see table). One of these two men had had a febrile illness with pneumonia three months before. This man, unlike some of the others, had never been abroad, and consequently it seemed

Gloucestershire, Wiltshire, Oxfordshire, and Denbighshire. The highest incidence has been in Kent, and the next highest in Devon. Possibly these findings are partly due to the more intensive investigation of these two counties because of the identification of the sources of the Cancer Hospital outbreak in them.

Preliminary accounts of the epidemiology of the outbreak of Q fever at the Royal Cancer Hospital have been included in papers by MacCallum et al (1949) and by Stoker and Marmion (1950). We describe here the epidemiological investigation in some detail and discuss the validity of the conclusions.

LABORATORY METHODS

Examination of Sera

Specimens of human and bovine sera were examined for Q fever antibodies by complement-fixation tests, the technique has been described by Stoker (1949). Human sera were inactivated at 56°C for 30 minutes, but bovine sera (obtained from the jugular vein) were inactivated at 60°C for 30 minutes, because it was found that treatment at the higher temperature reduced the number of specimens showing a low titre partial fixation, which was probably non specific.

A formalised purified yolk sac antigen made from the Henzlerling strain of *R. burneti* was used for all tests. At first this was supplied by Dr Cox, of Lederle Laboratories, New York, but later the strain itself was obtained and antigen was prepared at Cambridge by the technique used in Dr Cox's laboratory and described by Wolfe and Kornfeld (1949). No differences were detected in direct comparisons between the antigens made in the U.S.A. and England.

Large batches of human and bovine sera were first tested at a single dilution of 1/8 or 1/10, and those which showed fixation were retested over a range of dilutions to determine the end point. A titre of 1/10 was considered to be the lowest significant dilution, but higher titres were generally found in specimens from humans who had recently had Q fever, and from cows which were excreting *R. burneti* in the milk at the time.

Examination of Milk

Duplicate samples of about 15 ml of milk were taken into universal containers with rubber lined screw caps, and sent to the laboratory in a vacuum flask or insulated box packed with solid carbon dioxide. One sample was examined at the Department of Pathology, Cambridge, and the other at the Virus Reference Laboratory, Colindale. Milk was pooled in lots representing 2-4 farms for the initial examination, and the components of positive pools were later retested individually.

Two previously bled guinea-pigs weighing 300-500 g were injected with 3-4 ml of milk intraperitoneally and caged with an un inoculated control animal so that cross infection from animals in other cages might be detected. Rectal temperatures were recorded daily, and blood was removed for passage from some guinea-pigs which became febrile 8-15 days after inoculation. Test and control animals were killed and bled four weeks after inoculation, and the sera were subsequently tested in parallel with the pre inoculation samples for complement fixing antibodies to *R. burneti*. Provided the un inoculated controls showed no serological response, a rise in the titre from less than 1/5 in the first to more than 1/20 in the second specimen was taken to indicate infection with *R. burneti*.

ROYAL CANCER HOSPITAL OUTBREAK

The case numbers correspond to those used by Harman (1949). The outbreak can be divided into two probably unconnected episodes, consisting of 4 cases in July and 2 in September, 1949. The outbreak is described mainly in the sequence in which the investigation evolved.

On July 20, 1949, the Virus Reference Laboratory received specimens of serum and clotted blood from a nurse and a pathologist at the Cancer Hospital who had been diagnosed as pyrexia of unknown origin, possibly Q fever. Isolation studies and identification of the rickettsia occupied about a month, and the diagnosis of Q fever in the 2 cases was certain by the end of August. Epidemiological investigations were

the hospital. At this time the pathologist (case 1) and the nurse (case 2) had fully recovered from their attack of Q fever.

Case 1 was interviewed, and the date of onset of his illness was established as July 12. The incubation period of Q fever is usually about 19 days, with a range of 14 to 26 days. Case 1 had therefore been infected during the period June 17-28, probably on June 24 or 25. He kept a diary and could account for his movements outside the hospital during this period.

Case 2 had become ill on July 10-11, about a day earlier than case 1, and although she could not remember in detail her activities during the period June 12-29, when she was infected, it was clear that she had not visited any of case 1's list of places or entertainments outside the hospital. It therefore seemed probable, that both case 1 and case 2 had been infected inside the hospital.

Contact between case 1 and case 2 was not frequent as a consequence of their hospital duties, but nevertheless a common source of infection seemed likely because of the almost simultaneous onset of their illnesses. A possible common source of infection could have been a patient, and in view of case 1's work, which included the performance of necropsies among other clinical pathological duties, a search of the necropsy records was made for a patient who had died in X ward, where case 2 had been working, and who had been examined post mortem by case 1. There had been no necropsies from June 10 to June 20, from June 20 to June 27 there had been six, and then no more until July 14. Two of these six patients had come from X ward, but only one had been examined by case 1. This was case 5, whose autopsy had been done on the morning of June 25, and the cause of death had been recorded as cerebral thrombosis and lobar pneumonia. It was then discovered that case 2 had been in frequent attendance on this patient and had "laid him out" after his death on June 24.

The necropsy had also been attended by a mortuary attendant (case 3), and another doctor (case 4). On inquiry it was found that the mortuary attendant was ill with bronchitis and pneumonia in another hospital, and that the doctor had recently recovered from a mild febrile illness. Both were bled and had high titres of *R. burneti* antibodies, although their illnesses were not typical of Q fever. The onset of case 3's illness was about July 10, and case 4's about July 13, which was consistent with infection at about the same time as cases 1 and 2. The staff of the pathological department consisted of 15 persons: 3 doctors, 2 haematologists, 4 technicians, 1 mortuary attendant, 2 secretaries, 2 cleaners, and 1 boy. Only the two doctors (cases 1 and 4) and the mortuary attendant (case 3) who had attended the necropsy had had proved attacks of Q fever, the remaining 12 members of the department were well. Sera from the 4 technicians and the other doctor, whose daily work resembled in other respects that of cases 1, 3, and 4, showed no *R. burneti* antibodies. The terminal illness of the patient and his necropsy thus provided a possible common source of infection for the nurse, the two pathologists, and the mortuary attendant.

Case 5, a man aged 78, had been admitted to X ward on May 27 so that his dysphagia, thought to be due to a carcinoma, could be investigated. Eighteen days after admission he became febrile and signs of bronchopneumonia were found. This was not an unexpected complication, for his dysphagia led to the aspiration of food and fluids into his lungs. The bronchopneumonia did not respond to chemotherapy with penicillin and sulphonamides, and he died on June 24. The time relationship of case 5's illness to that of the other cases described above is shown in fig. 1. Later investigations by Whittick (1950) have shown that the gross and histological appearances of case 5's lung correspond to those

Fig 1—Time relation of illness of case 5 to onset of illness in cases 1-4

found in Q fever. This information was not available at the time, but investigations proceeded on the hypothesis that case 5 had had Q fever and that either he had been admitted to hospital during the incubation period of the disease, having been infected shortly before admission, or that he had been infected very shortly after admission. The period of eighteen days between admission and the onset of his illness was consistent with either possibility.

These alternatives of infection outside or inside the hospital were investigated concurrently, the first by a visit to case 5's home in Kent, the second by a search for any previous cases of Q fever among the patients in X ward or the staff of the hospital in general.

Of the 31 patients who had been in X ward at the same time as case 5, none had had a suspicious fever before the onset of his illness, and only 6 had had any fever between May 27 and June 24, when case 5 had been in the ward. In 2 patients the fever had clearly been related to a recent operation, and in the other 4 probably to their cancerous condition. Sera taken three or four months later from 5 of the patients who had been febrile were negative for *R. burneti* antibodies, the sixth patient had died shortly after discharge from hospital. All the 31 patients were followed up, and none had had any unexplained febrile illness after discharge from hospital. An attempt was made to examine the serum of each patient, and this was done with negative results in 22 patients, but in 5 cases blood could not be obtained owing to death since discharge, and 4 patients refused venepuncture.

The staff of X ward, other than case 2, consisted of a house physician, a sister, eight nurses, two ward orderlies, and two maids. None of these persons had been ill and all, except the house physician and the maids, who refused specimens, were serologically negative. There was no other illness clinically or serologically suggesting Q fever in the general staff of the hospital at this time, and no record of the importation of any likely source of Q fever, such as raw milk, raw dairy foods, and animal products, was found on inquiry at the hospital catering department.

It therefore seemed that case 5 had been admitted while incubating Q fever. It was also established that he had not been exposed to any suspicious case or possible source of Q fever during the journey on May 27 from his home in Kent to the Royal Cancer Hospital. The ambulance crew who had been with him on this journey were well and serologically negative.

EPIDEMIOLOGICAL STUDIES IN KENT

Early in September a visit was made to case 5's household, which consisted of his wife and two daughters, in a seaside town of N.E. Kent. Another married daughter and two married sons were occasional visitors. The three daughters and one son were quite well, and their

sera were negative. The other son was also well, but he lived in another part of the country, and his serum was not examined. Case 5's wife (case 6), however, was confined to bed with a vague illness complicated by cardiac failure, and her serum had a high titre of *R. burneti* antibodies (1/640). Her illness had started with diarrhoea on July 25, and a minor stroke followed on Aug 1. The clinical picture was not that of Q fever, and it was uncertain whether the *R. burneti* antibodies resulted from the illness or past exposure. She had not visited or seen her husband since he went to hospital or after his death, but had received letters from him.

Case 5 had been a jobbing tailor by trade but of recent years had only done work for neighbours and friends. He had neither history of occupational exposure to animals, as is found in some cases of Q fever, nor had he repaired any clothing soiled with animal excreta, handled packing straw, or recently received food parcels from abroad. There was a small retail dairy A about 100 yards from his house, and a butcher's shop with a sausage manufacturing plant at the back of the premises.

The investigations of Huebner et al (1948) in California showed that raw milk from many dairy herds was infected with *R. burneti*. So, since no other source of infection had been found to explain case 5's illness, his milk supply was investigated. His household was supplied by the small retail dairy A which received bulked heat-treated milk from London and some raw milk from local farms. These two milks were bottled at the dairy and sold separately, and it was impossible to find out which customers had raw and which had pasteurised milk, if, indeed, distribution was at all consistent. Dairy A and two other local dairies B and C, one (B) combined with a farm and both unconnected with case 5's household, were investigated. Volunteers were bled, and their sera were tested for *R. burneti* antibodies. At dairy A, 2 of the 8 volunteers had low titres of complement-fixing antibodies to *R. burneti*, and 6 of the 19 volunteers from dairies B and C were positive, 2 having titres of 1/80 (see table). One of these two men had had a febrile illness with pneumonia three months before. This man, unlike some of the others, had never been abroad, and consequently it seemed

c = cows — = *R. burneti* not isolated from milk of cow

certain that Q fever was present in the area, and that the illness of case 5 and his wife did not represent an isolated importation of *R. burnetii*.

Next, the seven local farms supplying dairy A were visited, some of the farm workers and cattle bled, and samples of the milk taken. Here again, serological positives were found among the farm workers and cattle. Two of the farm workers with the higher titres had had severe attacks of "influenza" during the previous six months or year. The table shows the distribution of the titres against *R. burnetii* found in the men and the cattle.

Finally, *R. burnetii* was isolated from the herd milk of two of the farms. Herd milks from all farms were tested on two occasions at a week's interval, and from the positive ones at intervals during five months. Farm W was positive on each of four tests covering a period of five months, and farm R was positive on each of three tests during a period of three months. Milks from dairies B and C were negative on guinea-pig inoculation. These tests were made nine months after the original visits to bleed the employees of dairies B and C. It is of interest, however, that in 3 recently discovered cases of Q fever the patients had had their milk from one or other of these two dairies.

Fig 2 summarises the position. It will be noted that in dairy A and its farms there was good agreement between the presence of *R. burnetii* in the milk and antibodies in man and cattle.

SECOND EPISODE AT ROYAL CANCER HOSPITAL

While the investigations in N E Kent were in progress, an unexpected development had taken place at the Royal Cancer Hospital. The staff had been closely watched for any secondary cases infected from the first 4 patients, although published evidence suggests that such spread is exceedingly rare in outbreaks of Q fever.

On Sept 10 the laboratory was told that a physician (case 7) working in an institute attached to the hospital, was ill with a condition clinically suggesting Q fever.

Fig 2—Distribution of antibodies to *R. burnetii* in district where case 5 had lived

The date of onset of case 7's illness was Sept 7, about two months after the first group of cases. His probable date of infection was therefore about Aug 20, with a range from Aug 13 to Aug 25. He had, however, been on holiday in Devon from Aug 1 to Aug 31. In addition his wife (case 8), who had not been in the hospital for over a year, had also become ill on Sept 9 with similar signs and symptoms. Because of the epidemiological improbabilities involved, the suggestion that these were fresh cases of Q fever was received with considerable scepticism, but a rising titre to *R. burnetii* in both patients soon justified the provisional clinical diagnosis.

The manner in which cases 7 and 8 had contracted Q fever could be explained in one of two ways: either they had been infected from the first group of cases by taking some contaminated article from the hospital on holiday with them, or they had been infected from some quite different source unconnected with the first group of cases. The only article case 7 could remember taking from the hospital was a cardboard box of tab codemaco. These had come from a ward unconnected with case 5 or the cases infected from him. This left the second possibility. Further inquiry revealed that between Aug 15 and Aug 20, cases 7 and 8 had made the acquaintance of a Devon farmer and been guests at his farm D several times. They had had meals, including liquid cream, at the farm and had been present at the delivery of a cow named "Tabor Lass." In November we heard from case 7 that case 9, a Devon resident who had also visited the farm and been present at the delivery of "Tabor Lass," was convalescing from atypical pneumonia, which had started on Sept 9. His serum was then examined and found to have a high titre to *R. burnetii*. With the kind assistance of various members of the Devon Epidemiological Society, 14 of the 40 cattle on the farm were bled, and 2 of them were found to have antibodies for *R. burnetii* in low dilution (1/10 and 1/20). One of the positive cows was "Tabor Lass." Pooled milks collected from the herd on Dec 2 were negative on guinea-pig inoculation. Unfortunately "Tabor Lass" was dry at that time, making it impossible to test her milk.

There was therefore a group of 3 cases starting about the same time and presumably infected from the same source. It is reasonable to suppose that this source was the farm or possibly some other place in the area where they had spent their holiday. If case 7 had been infected at the Royal Cancer Hospital, other cases might have been expected among the staff. Suggestive febrile illnesses in two other workers in the institute and in an anaesthetist were investigated and found not to be Q fever. Apart from these three persons there was no other illness among the staff at the hospital up to January, 1950.

DISCUSSION

The results of the epidemiological investigations just described could be interpreted as showing the spread of infection by devious routes from two farms to members of the staff of the Royal Cancer Hospital. However, certain links of this interesting chain of events must be examined more critically.

There can be little doubt that the immediate source of infection of the nurse, the two pathologists, and the mortuary attendant was case 5. Whittick's (1950) investigations have shown that the morbid anatomical findings in this patient strongly suggested Q fever. The onset of illness in the 4 patients was limited to a period of three days, indicating infection from a common source rather than spread from person to person, and case 5's death and necropsy provide a common factor linking the nurse and the pathologists. In addition, persons in the ward and pathological department who had not been closely exposed to case 5 did not contract Q fever.

The published accounts of the epidemiology of Q fever emphasise the rarity of infection of nurses and physicians

attendant on cases of Q fever, and in this exception to the rule there were undoubtedly special circumstances. The finding by Whittick (1950) of large numbers of rickettsia like organisms in case 5's lung is one that has not previously been described in other cases of Q fever. It may be that the presence of such large numbers made the patient more than ordinarily infectious. Towards the end of his illness case 5 was incontinent of urine and producing sputum which, owing to his dysphagia, he often regurgitated with his food. He was therefore a more "dirty" patient than the Q fever patients of previous studies, drawn from the Army or occupational groups, who had short illnesses, produced little sputum, and, although rickettsiae might be present in their urine, were not incontinent and could dispose of their urine in a hygienic way.

The nurse (case 2) had very close contact with case 5 when she "laid him out," and was the only person in X ward to contract the infection. "Laying out" presumably included much handling of bed clothes and pyjamas contaminated with excreta and food in addition to direct contact during the washing of the body. Oliphant et al (1949) have shown that rickettsia contaminated laundry can be a source of infection in Q fever.

In considering the mode of infection of the pathologists reference must be made to the conventional possibilities of infection via skin abrasions or the conjunctiva, but by analogy with the experience of persons working with infected animal material it is more probable that they were infected by the inhalation of small droplets formed during the removal and cutting of case 5's organs, in particular the lung. Sloan (1942) has shown that tubercle bacilli can be recovered from glass plates situated 8 inches away from the lung of tuberculous patients during necropsy. The handling of the lung in Sloan's experiments was gentle, no splashing occurred, but crepitation tests were done by gently squeezing the tissue. Probably such crepitation tests, or the natural retraction of the lung on cutting, would lead to the expulsion of air containing fine infected droplets. The pathologists at case 5's necropsy wore gowns and gloves, and a hose was not used to wash the organs: these were however, washed under the tap, with the result that some more obvious splashing must have occurred.

The manner in which case 5 was infected is not so clear. The incubation period of Q fever is usually taken to be about nineteen days. It therefore seems that case 5 was infected very shortly before his admission to hospital. The fact that his wife was serologically positive makes it probable that he was infected while living at home rather than during his journey to hospital. One other more remote possibility must be considered in passing—i.e., the accidental aspiration of barnum into his lungs during the investigation of his dysphagia shortly after admission (Harman 1949) provoked a change of a latent and more long standing infection with *R. burnetii* into an acute pneumonia. In these circumstances he might have been infected in the more remote past. Consultation with his family doctor has not however, revealed any past history of recurrent febrile episodes such as occurs in a minority of cases of Q fever. The only environmental source of *R. burnetii* which was found was the milk supply to case 5's household, and it is possible that consumption of this milk was responsible for the illness of case 5 and his wife. Before the significance of this finding can finally be assessed it is necessary to know something of the incidence of Q fever in those of case 5's neighbours who were consuming the same milk as compared with those using pasteurised milk from other sources. Such investigations are now in progress. Stoker (1950) shows that the strain isolated from the pathologist case 1 and presumably acquired from case 5 and another strain (M_1) isolated from case 5's

milk-supply, behave differently in their animal and egg pathogenicity. It seems improbable that two human passages would be sufficient to alter the characteristics of the human strain if it had originally come from the milk. At least three cows excreting *R. burnetii* contributed to the pool from which strain M_1 was isolated. Perhaps the strain M_1 and the strain infecting case 5 came from different cows. Nevertheless the difference between the human and milk strains underlines the need for caution in attributing case 5's infection to his milk supply.

In spite of the failure of milk to infect by the gastrointestinal route in experiments on volunteers (Fonseca et al 1949) the evidence that raw milk can be a source of infection is very strong. Bell et al (1950), in a brilliant epidemiological study of Q fever in California, showed that the incidence of serological positivity was 10.7% in raw milk drinkers as compared with 0.9% in control groups using only pasteurised milk. Whatever the time and source of case 5's infection, it is clear that he came from a place where the disease is endemic, this is proved by the subsequent discovery of other cases of Q fever in the same town, and by the fact that 16% of a sample of 83 blood donors in the town had serological evidence of previous infection.

The occurrence of the second group of cases in the Royal Cancer Hospital outbreak (cases 7, 8, and 9) is a remarkable coincidence, because no other cases of Q fever have been found during the examination of sera from more than 300 cases of atypical pneumonia in London. The evidence presented must lead to the conclusion, however remarkable, that cases 7 and 8 were not infected from the first group of cases at the Cancer Hospital but in Devon. Attendance at the delivery of the cow "Tabor Lass" may have been the occasion of infection. Luoto and Huebner (1950) have shown that placentas from 39% of 33 serologically positive cows contained *R. burnetii*, as many as 10^8 guinea-pig infective doses being present in some instances. There is no direct evidence that the placenta of "Tabor Lass" was infected, although her serum was positive, but the incident is suggestive. The discovery, in collaboration with the Devon Epidemiological Society, of other cases of Q fever in the same part of Devon establishes the county as another endemic area in which cases 7 and 8 could have acquired their infection.

The occurrence of a previously unsuspected disease always raises the question whether it is a recent importation. Little direct evidence can be brought on this point but it is perhaps worth noting that, in spite of the large numbers of cases which must, on the basis of serological surveys of dairy and farm workers and blood donors have occurred in the endemic areas, practitioners did not feel that there had been any undue incidence of fevers or pneumonias. Certainly many cases of Q fever must have been dismissed as "influenza," "brucellosis," and the like. The difficulty of recognising cases of Q fever on clinical grounds alone and their essentially sporadic distribution are adequate reasons for the failure to detect them in the past.

SUMMARY

The epidemiological investigation of an outbreak of Q fever at the Royal Cancer Hospital, London, is described.

The outbreak comprised two apparently unconnected episodes, the first consisting of four cases in July, 1949, and the second of two cases in September, 1949.

In the first episode a nurse, two pathologists, and a mortuary attendant were apparently infected during the terminal illness and at the necropsy of an unrecognised case of Q fever.

In the second episode, two months later, another member of the staff and his wife were infected while on holiday in Devon.

The fatal case of Q fever came from N E Kent, and the patient may have been infected there by the consumption of raw milk, which was shown to contain *R burneti*.

Other investigations, by the detection of more cases of Q fever and the demonstration of antibodies in farm workers and cattle, have shown that parts of Kent and Devon are areas where Q fever is endemic.

We wish to thank Dr B Lewis, resident medical officer at the Royal Cancer Hospital, for her helpful suggestions and co-operation. Dr C E Etheridge and Dr T A R Callender, Mr F W I Whitehouse, sanitary inspector, and Mr A J Beeson, Mr J Stewart, and Mr J Edwardson, veterinary inspectors, all of whom gave considerable help in the Kentish investigation. Dr B Moore, who gave valuable help and advice in Devon, and Mr J R McDonald, A.M.L.T., and Mr P H Phipps, A.M.L.T., at Colindale, and Miss Z Page, at Cambridge, for technical assistance.

Q FEVER IN GREAT BRITAIN

THE CAUSATIVE AGENT

M G P STOKER

M.D. Camb.

LECTURER IN PATHOLOGY, UNIVERSITY OF CAMBRIDGE

With illustrations on plate

The organism which causes Q fever was first described in 1937 by Burnet and Freeman working with a strain isolated in Queensland by Derrick (1937). The agent was shown to possess the general characteristics of a rickettsia and Derrick suggested the name *Rickettsia burneti*.

At about the same time Davis and Cox (1938) isolated a similar organism from the tick *Dermacentor andersoni* collected at Nine Mile Creek, Montana, U.S.A., and because it passed through filters which normally retained bacteria and other rickettsiae they named it *Rickettsia diapora*. Subsequently Burnet and Freeman (1939) and Dyer (1939) showed that these two organisms were identical and the name *Rickettsia burneti* was universally adopted. Despite its resemblance to other rickettsiae, *R. burneti* possesses some distinguishing features. For example, it may pass through filters with an average pore diameter as small as 400 mμ and it remains viable for long periods when stored without refrigeration—probably an important epidemiological feature. Philip (1948) has suggested that these differences are at a generic level and has proposed a new name, *Coxiella burneti* (Derrick), for the organism.

In the last few years Q fever has been identified, and *R. burneti* isolated, in several different countries, thus enabling strains from widely separated geographical areas to be compared. Strains originating in Italy, Greece, and Panama, as well as in Australia and the U.S.A., were compared by Robbins et al (1946) and Topping et al (1946). These studies showed that there was complete reciprocal cross immunity in guinea-pigs between the strains studied, but that Mediterranean and Australian strains produced a milder disease than American strains in these animals. Complement fixation

tests revealed that the sensitivity of antigens made from Mediterranean strains was much higher than those of the American strains. Mediterranean strain antigens revealed high antibody titres in sera from any strain, whereas American or Panama strain antigens would not react even with their own homologous antisera unless very high antigen concentrations were used. This was of great practical importance, since the Mediterranean strains were obviously preferable for diagnostic antigens and the Henzerling Italian strain was especially suitable in this respect.

It appeared, therefore, that strains of *R. burneti* could broadly be divided into two groups: (1) the American and Panama strains, and (2) the Mediterranean and probably Australian strains. The American strain used in these studies, however, was the Dyer strain, and Wolfe and Kornfeld (1949) have since reported that they could detect no antigenic difference between the original American Nine Mile strain isolated from ticks and the Italian Henzerling strain. Although no direct comparisons have been reported, it thus seems that these two American strains, Nine Mile and Dyer, are antigenically distinct in that the former resembles the Italian strain and the latter does not (Strauss and Sulkin 1949). This is particularly interesting because the Dyer strain was isolated from an individual supposedly infected with the Nine Mile strain in a laboratory. It seems unlikely that these fundamental differences have arisen simply from one human passage of the organism, and it is possible that this individual was actually infected, in the laboratory or elsewhere, with another strain altogether.

R. burneti was first isolated in Great Britain last year by MacCallum, Marmion, and Stoker (1949), and subsequently several strains have been obtained from raw milk in endemic areas by Marmion and Stoker (1950). This paper reports a laboratory study of the original human (Christie) strain and the first milk strain to be isolated (M1 strain), and a comparison of both with the standard Italian (Henzerling) strain.

MATERIALS AND METHODS

Strains of *R. burneti*

The original isolation of the Christie strain from a human case of Q fever has been described elsewhere (MacCallum et al 1949). The other strain (M1) was obtained from a pool of raw milk collected from three farms in north Kent during the epidemiological investigation described by Marmion and Stoker (1950).

Two (previously bled) guinea-pigs were inoculated intraperitoneally with 4 ml of the milk pool, and both developed fever fifteen days later. One guinea-pig was killed immediately and its heart blood was passed to fresh guinea-pigs. The second guinea-pig was bled nineteen days after the onset of fever, and it was found to have developed Q fever complement-fixing antibodies. An uninoculated guinea-pig in the same cage developed no fever or antibodies.

These indigenous strains of *R. burneti* were compared with the Henzerling strain* isolated from a soldier in Italy by Robbins et al (1946). This was chosen because it is the strain most commonly used for antigen preparation, and because it has been studied extensively and compared with other strains from different parts of the world (Topping et al 1946).

Male or female guinea-pigs weighing 400–500 g were used for most of the animal experiments and were inoculated intraperitoneally. Their rectal temperatures were recorded daily and a temperature of over 103.5°F was regarded as abnormal. Citrated heart-blood withdrawn on the second or third day of fever was generally used for passage to further guinea-pigs in 3–4 ml quantities but 10% spleen emulsion was sometimes used instead. All mice used were of the Glaxo MM strain.

Fertile hens' eggs (White Leghorn) were incubated at 37°C for six days before the inoculation into their yolk sacs.

TABLE 1—SUMMARY OF THE BEHAVIOUR OF THREE STRAINS OF *R. burneti* IN GUINEAPIGS

Strain	Inoculated with guinea pig heart blood or spleen					Inoculated with infected yolk sac				
	Passage nos	No of guinea pigs	No developing fever	Mean incubation period (days)	Mean duration of fever (days)	No of deaths	No of guinea pigs	No developing fever	Mean incubation period (days)	Mean duration of fever (days)
Christie	2-12	30	27	7.5*	2.0*	1	10	10	3.9	4.7
M1	2-12	25	24	5.8*	3.8*	0	6	6	2.6	4.8
Henzerling	1-6	20	18	7.7	2.8	0	10	9	3.3	3.4

* Standard error of the difference between mean incubation periods of Christie and M1 strains = 0.61 and between mean durations of fever = 0.62

of 0.25 ml quantities of infected material. The eggs were subsequently incubated at 35°C, with candling twice daily. Deaths occurring in the first three days were probably due to trauma or bacterial contamination and these eggs were discarded. Subsequently all moribund or dead eggs were cultured for bacterial infection, the yolk sacs were harvested and impression smears made and fixed in methyl alcohol. For passage a 50% suspension of bacteriologically sterile yolk sac was generally used.

For preparing tissue suspensions 10% horse-serum broth was used throughout, and infected material was generally stored at -24°C, but seed suspensions consisting of specially selected, heavily infected yolk sacs were kept at -70°C in sealed glass ampoules. Routine tests of animal or egg material for bacteriological sterility were made aerobically on blood agar, but sometimes additional cultures were made anaerobically and in 10% CO₂.

Smears and sections of infected tissues were stained with Giemsa stain. Early passage yolk sac smears were stained by Macchiavelli's technique, but this was found to be less satisfactory than Giemsa stain and was eventually discarded.

Owing to the frequency of human laboratory infection with *R. burneti*, infected animals were kept in small isolated huts on the roof of the department, another hut served as a small laboratory for manipulation of infected material, where all eggs were harvested inside an enclosed inoculation chamber. Laboratory personnel who were likely to visit these huts were inoculated with Q fever vaccine.

EXPERIMENTAL STUDY

Behaviour in Animals

Both English strains and the Italian strain of *R. burneti* caused a mild febrile illness in guinea pigs resembling that described by other workers with this organism. The incubation period for the first passage in guinea pigs was twenty two days for the Christie strain and fifteen days for the M1 strain, but during subsequent passages it was usually four to ten days. The febrile period generally lasted one to five days with temperatures up to 106°F, followed by complete recovery. Out of 75 animals used for routine guinea pig passage only 1 died spontaneously. This had been inoculated with the Christie strain, and although no bacterial cause of death was demonstrated it was not possible to prove that *R. burneti* was responsible.

Table 1 summarises guinea pig passages 2 to 12 of the Christie and M1 strains and 6 passages of the Henzerling strain. It will be noted that over the same passages the mean incubation period for the Christie (human) strain was greater than that for the M1 (milk) strain, and

statistical analysis shows that this difference was unlikely to be due to chance. Similarly, there is a significant difference in mean lengths of fever between the Christie and M1 strains, all of which suggests that the M1 strain was slightly more pathogenic for guinea pigs than the Christie strain. Occasionally inoculated animals did not develop fever, but it was possible to demonstrate that Q fever complement fixing antibodies had developed in these as well as in the febrile guinea pigs.

In guinea pigs killed during or after the febrile period no abnormality could regularly be found except enlargement and increased friability of the spleen. No rickettsiae could be demonstrated in Giemsa stained smears from peritoneum or spleen.

Guinea pigs inoculated with large numbers of viable organisms of the Christie or M1 strain in suspensions of infected yolk sac developed a more severe illness with a shorter incubation period (one to six days) and longer fever (table 1). Although no deaths resulted from inoculation of the Henzerling strain in this way, most of the animals infected with English strains died either at the height of the fever or after the temperature had returned to normal for several days.

Post mortem examination after these late deaths revealed the most marked changes. There was usually emaciation, an enlarged and friable spleen, congestion and thickening of the peritoneum with a scanty blood stained exudate, and in most instances a patchy consolidation of both lungs. Giemsa stained smears from the peritoneum revealed large numbers of extracellular and intracellular rickettsiae (fig. 1). Microscopically there was a perivascular cuffing of small blood vessels by macrophages and lymphocytes, particularly in the lung and liver. This change was mainly around the portal vessels in the liver and was sometimes accompanied by a localised periportal necrosis. There were occasionally areas of frank mononuclear cell consolidation in the lung, but rickettsiae could only rarely be seen in Giemsa stained sections. The surface of the spleen showed a well marked mononuclear cell exudate, in which intracellular rickettsiae could be seen in large numbers, but the organisms were also present in macrophages in the substance of the spleen.

Mice inoculated with heart blood from guinea pigs infected with the Christie strain remained well, but those inoculated with heavily infected yolk sac suspensions died in twelve to fourteen days with peritoneal exudate and enlarged spleens.

Growth in the Fertile Hen's Egg

The English strains of *R. burneti* resembled most other pathological rickettsiae in their ability to multiply freely in the yolk sacs of fertile hen's eggs.

Fig. 5—Serial yolk-sac passages of Christie and M1 strains of *R. burneti* showing average day of death of embryos at each passage. (Passages 2 and 3 of the Christie strain included survivors 14 days after inoculation.)

The fatal case of Q fever came from N E Kent, and the patient may have been infected there by the consumption of raw milk, which was shown to contain *R burneti*.

Other investigations, by the detection of more cases of Q fever and the demonstration of antibodies in farm workers and cattle, have shown that parts of Kent and Devon are areas where Q fever is endemic.

We wish to thank Dr B Lewis, resident medical officer at the Royal Cancer Hospital, for her helpful suggestions and co-operation, Dr C E Etheridge and Dr T A R Callender, Mr F W I Whitehouse, sanitary inspector, and Mr A. J. Beeson, Mr J Stewart, and Mr J Edwardson, veterinary inspectors, all of whom gave considerable help in the Kentish investigation, Dr B Moore, who gave valuable help and advice in Devon, and Mr J R McDonald, A.I.M.L.T., and Mr P H Phipps, A.I.M.L.T., at Colindale, and Miss Z Page, at Cambridge, for technical assistance.

Q FEVER IN GREAT BRITAIN

THE CAUSATIVE AGENT

M G P STOKER

M D Camb

LECTURER IN PATHOLOGY, UNIVERSITY OF CAMBRIDGE

With illustrations on plate

The organism which causes Q fever was first described in 1937 by Burnet and Freeman working with a strain isolated in Queensland by Derrick (1937). The agent was shown to possess the general characteristics of a rickettsia and Derrick suggested the name *Rickettsia burneti*.

At about the same time Davis and Cox (1938) isolated a similar organism from the tick *Dermacentor andersoni* collected at Nine Mile Creek, Montana, U.S.A., and because it passed through filters which normally retained bacteria and other rickettsiae they named it *Rickettsia diaporica*. Subsequently Burnet and Freeman (1939) and Dyer (1939) showed that these two organisms were identical and the name *Rickettsia burneti* was universally adopted. Despite its resemblance to other rickettsiae, *R. burneti* possesses some distinguishing features. For example, it may pass through filters with an average pore diameter as small as 400 mμ and it remains viable for long periods when stored without refrigeration—probably an important epidemiological feature. Philip (1948) has suggested that these differences are at a generic level and has proposed a new name, *Coxiella burneti* (Derrick), for the organism.

In the last few years Q fever has been identified, and *R. burneti* isolated, in several different countries, thus enabling strains from widely separated geographical areas to be compared. Strains originating in Italy, Greece, and Panama, as well as in Australia and the U.S.A., were compared by Robbins et al (1946) and Topping et al (1946). These studies showed that there was complete reciprocal cross immunity in guinea-pigs between the strains studied, but that Mediterranean and Australian strains produced a milder disease than American strains in these animals. Complement fixation

tests revealed that the sensitivity of antigens made from Mediterranean strains was much higher than those of the American strains. Mediterranean strain antigens revealed high antibody titres in sera from any strain, whereas American or Panama strain antigens would not react even with their own homologous antisera unless very high antigen concentrations were used. This was of great practical importance, since the Mediterranean strains were obviously preferable for diagnostic antigens and the Henzerling Italian strain was especially suitable in this respect.

It appeared, therefore, that strains of *R. burneti* could broadly be divided into two groups: (1) the American and Panama strains, and (2) the Mediterranean and probably Australian strains. The American strain used in these studies, however, was the Dyer strain, and Wolfe and Kornfeld (1949) have since reported that they could detect no antigenic difference between the original American Nine Mile strain isolated from ticks and the Italian Henzerling strain. Although no direct comparisons have been reported, it thus seems that these two American strains, Nine Mile and Dyer, are antigenically distinct in that the former resembles the Italian strain and the latter does not (Strauss and Sulkin 1949). This is particularly interesting because the Dyer strain was isolated from an individual supposedly infected with the Nine Mile strain in a laboratory. It seems unlikely that these fundamental differences have arisen simply from one human passage of the organism, and it is possible that this individual was actually infected, in the laboratory or elsewhere, with another strain altogether.

R. burneti was first isolated in Great Britain last year by MacCallum, Marmion, and Stoker (1949), and subsequently several strains have been obtained from raw milk in endemic areas by Marmion and Stoker (1950). This paper reports a laboratory study of the original human (Christie) strain and the first milk strain to be isolated (M1 strain), and a comparison of both with the standard Italian (Henzerling) strain.

MATERIALS AND METHODS

Strains of *R. burneti*

The original isolation of the Christie strain from a human case of Q fever has been described elsewhere (MacCallum et al 1949). The other strain (M1) was obtained from a pool of raw milk collected from three farms in north Kent during the epidemiological investigation described by Marmion and Stoker (1950).

Two (previously bled) guinea-pigs were inoculated intra-peritoneally with 4 ml of the milk pool, and both developed fever fifteen days later. One guinea-pig was killed immediately and its heart-blood was passed to fresh guinea-pigs. The second guinea-pig was bled nineteen days after the onset of fever, and it was found to have developed Q fever complement-fixing antibodies. An uninoculated guinea-pig in the same cage developed no fever or antibodies.

These indigenous strains of *R. burneti* were compared with the Henzerling strain* isolated from a soldier in Italy by Robbins et al (1946). This was chosen because it is the strain most commonly used for antigen preparation, and because it has been studied extensively and compared with other strains from different parts of the world (Topping et al 1946).

Male or female guinea-pigs weighing 400–500 g were used for most of the animal experiments and were inoculated intraperitoneally. Their rectal temperatures were recorded daily and a temperature of over 103.5°F was regarded as abnormal. Citrated heart-blood withdrawn on the second or third day of fever was generally used for passage to further guinea-pigs in 3–4 ml quantities, but 10% spleen emulsion was sometimes used instead. All mice used were of the Glaxo MM strain.

Fertile hens' eggs (White Leghorn) were incubated at 37°C for six days before the inoculation into their yolk sacs.

rickettsiae, is again centrifuged and treated with cold ether overnight. This is followed by repeated ether treatment at room temperature until no interphase is present between the ether and aqueous layers. The rickettsiae in the aqueous layer are finally washed three times by high speed centrifugation and resuspended in 1/15th of the original volume of buffered formal saline. This results in a concentrated and highly purified preparation of rickettsiae.

Convalescent serum from Dr A C Christie, from whom the strain was isolated, was used as a standard antiserum, but guinea-pig antisera were also used. Tests with antigen were generally put up in a chessboard fashion.

Antigen prepared from the Henzerling strain has been used throughout for routine diagnosis of Q fever and for epidemiological studies. Different batches of antigen when titrated with Christie serum produce almost identical antiserum titres and antigen titres varying from 1/40 to 1/160. The optimal antigen concentration is usually 1/10 or 1/20.

The first antigens made from the Christie strain (egg passage 6) and the M1 strain (egg passage 4) were rickettsial suspensions which looked microscopically at least as pure and as concentrated as Henzerling strain antigens. Despite this they reacted poorly or not at all with Christie antiserum. Tests with a Christie strain guinea-pig serum also showed much higher serum titres with Henzerling than Christie antigen, and at this stage it was thought that the English strains might resemble the Panama or the Dyer American strain which react poorly even with homologous antisera.

Further passage of the Christie and M1 strains in yolk sacs, however, eventually yielded rickettsial antigens which did react with Christie antiserum, though the antigen titres were lower than those given by the Henzerling strain. Table IV shows the results of a titration of Christie serum in the presence of Henzerling antigen; Christie strain antigen from passages 6 and 11, M1 strain antigen from passages 4 and 5, and an antigen prepared by the same technique from normal yolk sacs (inoculated with 10% horse serum broth). Except for the normal egg antigen, which was completely clear, the suspensions were matched to a standard opacity.

* Not in same series

and checked microscopically so that they contained approximately equal numbers of rickettsiae.

The Christie antiserum reacted to 1/160 with the heterologous Henzerling antigen, but only to 1/5 with the homologous Christie antigen made from the 6th yolk-sac passage. After a further five passages in eggs, however, Christie antigen produced the same antiserum titres as the Henzerling antigen, though the antigen titre was only 1/10, compared to a Henzerling antigen titre of 1/40. Fourth-passage M1 strain antigen did not react at all with Christie serum, but 5th passage antigen (not in the same egg-passage series) reacted at low antigen and antiserum dilutions.

It is possible that, despite precautions, the English strains became contaminated by the Henzerling strain during yolk sac passage. This explanation is unlikely because the mean day of death of the adapted English strains remained at six to seven days, whereas under similar conditions the Henzerling strain generally killed the embryos in about four days.

These titrations were all put up together and the earlier passage antigens had therefore been stored at 2°C for longer than the antigens made from later passages. The early passage antigens, however, had also been tested immediately after preparation with the same negative results. There was no apparent difference in morphology or numbers of rickettsiae seen in Giemsa stained smears of the original yolk sacs or of purified antigens from either early or late passage.

Assuming that the rickettsial suspensions were of approximately equal concentration and purity, the results suggest that there was some change in antigenic structure during passage of the English strains in eggs, with the result that the sensitivity of the antigens was greater after increasing egg adaptation.

DISCUSSION

Under laboratory conditions the two strains of rickettsiae isolated in England closely resemble other known strains of *B. burnetii*, and in particular the Henzerling Italian strain. They caused a typical febrile illness in guinea-pigs, with development of specific antibodies and animals which had previously been infected with either of the English strains were immune to the classical Henzerling strain, and vice versa. The rickettsiae grew freely in the yolk sac of fertile eggs, and no difference in morphology or size between strains could be detected even by electron microscopy. The Christie strain was found to pass through gradacol membranes with an average pore diameter of 400 mμ, a feature which differentiates *R. burnetii* from other pathogenic rickettsiae.

During normal passage the illness caused by English strains in guinea-pigs was very mild and resembled that caused by the Henzerling strain, so that in this respect they probably differ from the American strains. When heavily infected yolk sac suspensions were inoculated intraperitoneally, however, the English strains often killed the guinea-pigs while those inoculated with the Henzerling strain survived. The English strains also differed from the Henzerling strain in their lethal effect on eggs. Even after eleven passages the Christie strain took an average of six to seven days to kill embryos, whereas the Henzerling always took four to five days. This was probably due to the much longer period of laboratory adaptation which the Henzerling strain had undergone.

A further difference between the English and Henzerling strains associated with egg adaptation was their behaviour as complement fixing antigens. Despite the presence of large numbers of rickettsiae, purified antigens from early passages of the English strains failed to react with homologous human antiserum except in very low dilutions, though the Henzerling antigen reacted to high

Yolk sac passage of the Christie strain was started at the Central Public Health Laboratory, Colindale, London, from first passage guinea-pig spleen and was continued in Cambridge from a yolk sac of the first egg passage at Colindale. Cultivation of the M1 strain in yolk sacs was started by inoculation of a 10% spleen suspension from the 5th guinea-pig passage of this strain.

The Henzerling strain was reconstituted from a lyophilised suspension of infected yolk sac and inoculated directly into eggs.

During the early passages of the Christie strain at Cambridge (2nd and 3rd egg passage) most of the eggs survived. After the 4th egg passage, however, all inoculated eggs died, and the interval between inoculation and death was gradually reduced until after the 6th passage when the average remained at six to seven days after inoculation of 50% yolk sac suspension (fig. 5).

Egg adaptation of the M1 strain was more rapid, and even in the early passages all the eggs died. The average day of death fell to four days in the 3rd passage, but thereafter remained like the Christie strain at six to seven days. Under similar conditions the Henzerling strain, already adapted to growth in eggs, usually killed the embryos four to five days after inoculation.

Very large numbers of rickettsiae were visible in Giemsa stained smears from the 2nd passage of the M1 strain and the 5th passage of the Christie strain. These organisms were almost entirely extracellular and they resembled rickettsiae seen in stained smears of the Henzerling strain, but in smears of English strains there was a greater tendency to aggregate into clumps. These clumps were of varying sizes and usually unattached to host cells, though the organisms may have been lying in pieces of cytoplasm which had broken away from disintegrating and heavily infected cells. The degree of clumping varied from egg to egg through all passages of the English strains but was more noticeable than with the Henzerling strain.

Size of the Organism

The size of the Christie strain organisms was estimated by filtration and by direct measurement of particles photographed with an electron microscope.

Three batches of a 2% suspension of heavily infected yolk sac were passed through gradacol membranes with average pore diameters of 640 μ , 400 μ , and 190 μ . Into each of 4 guinea-pigs, from which a sample of blood had previously been taken, 2.5 ml of each filtrate was

TABLE II—RESULTS OF FILTRATION OF CHRISTIE STRAIN OF *R. burneti*

Average pore diameter of filter	Guinea-pig nos	Complement fixing titre with Q fever antigen	
		Before inocula	After inocula
190 μ	2029 30 31 32	All < 1 5	All < 1 5
400 μ	33 34 35 36	All < 1 5	All > 1 20
640 μ	37 38 39 40	All < 1 5	All died of Q fever

inoculated intraperitoneally. Two weeks later all the guinea-pigs which had been inoculated with the 640 μ filtrate died. Large numbers of rickettsiae were present in peritoneal smears, no bacteria could be isolated from the spleens, and it was assumed that these animals had died of Q fever. The remaining guinea-pigs were bled a month after inoculation, and both pre inoculation and post inoculation specimens of serum were examined for Q fever complement fixing antibodies (see table II). None of the guinea-pigs inoculated with the 190 μ filtrate had serological evidence of infection, but all those inoculated with the 400 μ filtrate had developed antibodies since inoculation.

The organism therefore passed a 400 μ filter, and this implies that some infective particles had a diameter of less than about 300 μ .

Direct measurements by electron microscopy were made on purified suspensions of rickettsiae which were to be used as antigens. Figs 2, 3, and 4 (on plate) show gold shadowed organisms of the Christie and Henzerling strains. The strains resemble one another closely and have the typical structure of rickettsiae as seen under the electron microscope. They are mostly coccobacillary in form with an irregular central core surrounded by a flat apparently collapsed zone and a well marked limiting membrane. Fig 4, with the greatest magnification, shows one organism whose central portion seems to consist of a twisted thread like structure.

TABLE III—RESULTS OF CROSS IMMUNITY TESTS WITH THREE STRAINS OF *R. burneti* IN GUINEAPIGS. FIGURES INDICATE DURATION OF FEVER IN DAYS FOR INDIVIDUAL ANIMALS

Challenging strain	Duration of fever				
	Normal guinea-pigs	Guinea-pigs previously infected with—			
		Christie	M1	Henzerling	
Christie	2 3 3, 5 7 7 7		0 0 0, 0, 0	0 0 0	
M1	4 4 5 5 7	0 0 0 0 0		0 0	
Henzerling	2 2, 3	0, 0 0	0, 0 1		

Eighteen Henzerling and eleven Christie strain organisms were measured. The mean for the Henzerling strain was 600 μ $\times$ 210 μ , and for the Christie strain 600 μ $\times$ 200 μ , so there was no significant difference in the mean sizes of the two strains, though there was considerable individual variation in size and shape in both strains.

SEROLOGICAL TESTS

Cross immunity Tests

Cross immunity tests between the three strains were carried out in groups of guinea-pigs which had been infected with *R. burneti* during the routine passage of the strains. At various times these guinea-pigs had all shown a typical febrile response after the primary inoculation. Two to eight weeks later they were challenged by intra peritoneal inoculation of the heterologous strains, 2 ml of 1:1000 yolk sac suspension of each strain was used for the principal experiment, but in a preliminary test 2 ml of infected guinea-pig heart blood was the inoculum. Re inoculation with the homologous strains was not performed. Guinea-pigs with no previous exposure to *R. burneti* were inoculated as controls. The rectal temperatures were recorded for three weeks and it was assumed that a temperature of over 103.5°F occurring more than two days after inoculation indicated infection.

The duration of fever in days is recorded in table III. It will be seen that all the normal guinea-pigs developed fever lasting two to seven days. The immunised guinea-pigs remained afebrile during the whole three weeks, except for 1 animal previously infected with the M1 strain which developed fever ten days after re inoculation with Henzerling strain. With this exception there was complete reciprocal cross immunity between the three strains.

Complement fixation Tests

As soon as the English strains of *R. burneti* were sufficiently adapted to growth in fertile eggs, antigens were prepared from formolised suspensions of heavily infected yolk sacs. The rickettsial suspensions were purified by a modification of Topping's technique used by Wolfe and Kornfeld (1949).

This consists of high speed centrifugation of 20% yolk sac suspension and overnight cold ether extraction of the resuspended deposit. The aqueous phase, which contains the

transurethrally with the evacuator. The other 2 required cystotomy, and 1 of these subsequently died of uræmia despite intensive treatment.

Convalescence in several cases was delayed by suprapubic leakage but was invariably overcome by inserting an indwelling catheter for a few days. Serious wound infection with persistent fistula was not encountered.

Incontinence for a short time was common but it persisted in only 2 cases.

In 1 case it was impossible to find a plane of cleavage at operation. When the prostate gland was eventually enucleated, a portion of the prostatic membranous urethra was seen to have been avulsed with the gland mass. The technical difficulties of the operation were subsequently explained by the histological report, which revealed malignancy.

The other case of persistent incontinence was in a man, aged 65, with simple hypertrophy. Periodic instrumentation had no beneficial effect, and five months later he was readmitted and underwent transurethral resection of residual tags. However, this was only partially effective, and he still has recourse to a penile clamp.

The prostate was examined histologically in all cases. 5 proved malignant, and 1 was equivocal. Clinical examination in these 5 patients had never aroused more than a suspicion of malignancy, so the incidence of latent carcinoma was 8%. But this is rather less than in some of the published series.

The average length of stay in hospital was twenty-one days, but this does not do justice to the method, since this figure includes patients whose stay was prolonged by factors which would have operated against them whatever the method of therapy. For instance, one developed acute retention after the plating of a fractured tibia, another had multiple vesical calculi, and several were retained because of concomitant respiratory disease. Moreover, the patients' relatives could not always be persuaded to welcome them home as soon as the wound was healed. Most of them were fit for discharge in twelve to sixteen days.

MORTALITY

Of the 60 patients treated in this way during twelve months, 4 died, giving a mortality rate of 6.7%. One man, aged 74, died within a few hours of operation apparently from shock; necropsy revealed bilateral hydronephrosis and pyelonephritis. Another death occurred from pulmonary embolism in a man aged 75 who had been catheterised intermittently for three days before admission. A third death, due to uræmia following clot retention, occurred on the thirteenth postoperative day in a man aged 67. The fourth death was due to postoperative bronchopneumonia in a man aged 81.

CONCLUSION

A mortality rate of nearly 7% may be regarded as too high to justify this method of treatment. However, with one exception all the deaths were in men considerably over the age of 70. Moreover it should be possible to reduce the death rate somewhat as the selection of cases becomes more familiar, only 1 death occurred in the last 32 of the series.

The relatively high incidence of clot retention is possibly related to the engorgement of the prostate gland consequent on the advent of acute retention.

The considerable reduction in length of stay in hospital seems to justify extended trial of immediate operation.

My thanks are due to Mr. A. W. Adams, director of the genito-urinary department, United Bristol Hospitals, who has had charge of the cases described and performed most of the operations.

MEDICAL FIRST ASSISTANT

ROYAL INFIRMARY, SHEFFIELD

Most of the published reports on the treatment of typhoid fever with chloramphenicol describe relapses, but none of them seems to have demonstrated an increased drug resistance of the organisms during the relapse. Indeed, Good and Mackenzie (1950) and Rankin and Grimble (1950) showed in their cases that the sensitivity to chloramphenicol remained the same in cultures obtained before, during, and after treatment and relapse.

We report here a case of typhoid fever which relapsed during treatment with chloramphenicol and in which increased drug resistance of the infecting organism was established.

CASE-RECORDS

A married male nurse, aged 43, who had never received T.A.B. inoculation, was admitted to the Royal Infirmary, Sheffield, on Feb. 27, 1950, with two weeks' history of malaise followed by persistent fever, rigors, pains in the knee joints, and occipital and retro orbital headache. His appetite had been poor, and his bowels, normally regular, had been constipated for a week. In the two weeks before admission he had received courses of sodium salicylate and sulphadiazine ('Sulphamezathine') without any improvement.

On admission his temperature was 104.2°F, pulse rate 98, and respirations 20 per minute. He was haggard, ill, faintly cyanosed, resistant, and uncooperative and resented questioning and examination. No rash was present, the tongue was moist and moderately furred. The heart was not enlarged and the heart sounds were pure. The blood pressure was 124/72 mm. Hg. The activity of the alkaline phosphatase was obvious, but no abnormal signs were present in the lungs. The abdomen was not tender or distended, and the spleen was not palpably enlarged. No abnormality was detected on rectal examination.

Investigations.—Blood count on day of admission: Hb 15.5 g per 100 ml (105%), red cells 4,970,000 per c.mm., and white cells 4000 per c.mm. (polymorphs 51%, lymphocytes 41%, monocytes 6%, eosinophils 2%). Erythrocyte sedimentation rate (E.S.R.) 6 mm in 1 hr (Wintrobe).

Urine: trace of albumin, sterile on culture.

Radiography of chest: only "increased lung markings" at right base.

Blood agglutinations (Feb. 28): *Salmonella typhi* 0, 1/320, H, 1/1280. Vi 1/60.

Blood culture (Feb. 28): pure growth of *S. typhi*.

Fæces (March 1): a heavy growth of *S. typhi* sensitive to 12 µg of chloramphenicol per ml.

Treatment and Progress.—In the interval of two days between collection of the blood samples and establishment of the diagnosis, penicillin was given intramuscularly in full doses without any improvement. On March 1 rose spots appeared on the patient's abdomen. His fever persisted, he began to pass frequent liquid stools, and his general condition deteriorated.

Chloramphenicol was started on March 2, 2 g being given in the first two hours and then 0.5 g four hourly.

On March 3 the patient was cold and collapsed, blood pressure 100/60 mm. Hg. He became increasingly confused and uncooperative and drip feeding by indwelling gastric tube was instituted because he refused to drink and would not swallow tablets. Definite signs of consolidation now developed at the right lung base, and radiography confirmed the presence of right basal pneumonia. Pyrexia continued, and on March 7 the chloramphenicol was increased to 4 g daily. Blood culture was negative for *S. typhi* on this date.

In the next few days the patient's temperature fell steadily, and by March 10 eight days after the start of chloramphenicol though he was still readily dyspnoeic, he could take solids and fluids by mouth and his temperature was normal for the first time since admission. On March 12 the dosage of

titre When antigens of similar rickettsial concentration were made from later passages of English strains, they reacted satisfactorily with homologous antiserum. It is possible that egg adaptation brought about a change in antigenic structure characterised by increased sensitivity as complement fixing antigens. This might be of practical importance because the preparation of satisfactory antigens would depend on egg adaptation considerably past the passages where large numbers of rickettsiae were first visible in stained smears. Judging by antigens prepared at this stage the English strains resembled the Dyer Panama low sensitivity group of Topping et al (1946), but after further passage the increased sensitivity made this supposition untenable.

A difference between the two English strains themselves was in adaptation to growth in yolk sacs. This was much more rapidly achieved by the M1 strain from milk than by the Christie human strain, but this might have been due to the greater number of guinea-pig passages undergone by the M1 strain before transfer to eggs. Judging by the shorter incubation period and longer fever, the M1 strain was also slightly more pathogenic for guinea-pigs. These differences, between two strains only, may not be significant, but Dr E H Lennette informs me in a personal communication (1950) that he and his group in California have also found that strains of *R. burnetii* isolated from milk adapt more easily to yolk sac and guinea-pig than strains from humans or ticks.

These minor strain characteristics of *R. burnetii* isolated in Britain do not give any clear indication of a closer relationship to either European or American strains. In fact, the known characteristics of different strains of *R. Burnetii* are probably too indefinite to permit such an identification.

SUMMARY

Two strains of *R. burnetii* isolated in Great Britain have been studied under laboratory conditions. The Christie strain was obtained from a patient and the M1 strain from a pool of raw milk collected in an endemic area. These strains have been compared with the classical Henzerling strain isolated from a patient in Italy.

In their morphology, size, and general behaviour in guinea-pigs and fertile hen's eggs the British strains resembled the classical strain. There was also reciprocal cross immunity between all three strains in guinea-pigs.

Minor differences between the strains were detected. Judging by incubation period and length of fever, the British milk strain was more pathogenic for guinea-pigs and also adapted itself more rapidly to growth in fertile eggs than the human strain. Even after adaptation to eggs, however, the British strains took longer to kill the embryos than the classical strain.

Complement fixation tests showed that antigens made from the classical strain reacted with antisera against British strains. These British antisera, however, would not react with antigens made from either British strain until the strains had undergone several yolk sac passages. This effect was not related to the numbers of rickettsiae in the antigens and suggested a change in antigenic structure during egg adaptation.

Thanks are due to Dr V E Coslett and Mr R Horn for the electron microscopy, and to Miss Z Page for valuable technical assistance.

IMMEDIATE RETROPUBIC PROSTATECTOMY IN ACUTE RETENTION

FRANK R HURFORD
 M B Brist, F.R.C.S.

LATE GENITO URINARY REGISTRAR, UNITED BRISTOL HOSPITALS

IMMEDIATE prostatectomy for acute retention of urine has been extensively practised by Wells and others, using the Wilson Hey technique of suprapubic dissection with excision of the trigone. In selected cases the retropubic method can also be used with satisfactory results, as advocated by Walters (1949).

In the present series not all the patients with acute retention of prostatic origin underwent retropubic prostatectomy. The small fibrotic gland and the obviously malignant case were dealt with by transurethral resection. Adequate general physical capacity, assessed more from the patient's recent history than by any special clinical tests, was also an essential prerequisite. Provided the patient was still ambulant and active up to the onset of retention, operation was not necessarily refused because of chronic bronchitis or signs of cardiovascular degeneration. The blood urea was estimated in all the cases. Generally a figure over 100 mg per 100 ml was taken as a contra indication to immediate prostatectomy, but a few cases were operated on successfully with blood ureas considerably higher than this. Patients with obvious urethritis due to repeated catheterisations before admission were not subjected to immediate prostatectomy. Using these criteria the operation was performed in about 70% of all patients admitted with acute retention of prostatic origin. Age in itself was no contra indication, the oldest patient being 83.

PREOPERATIVE MANAGEMENT

When the patient was in great discomfort, a suprapubic spinal needle was inserted on admission, but there may be considerable extravasation of urine into the retro pubic space if operation is not done within a few hours.

Latterly all the patients received streptomycin, the first dose of 0.5 g being given an hour before operation, as advocated by Wilson Hey. All of them had their blood grouped, but none received transfusion or infusion before operation, and only a minority needed transfusion after it.

OPERATIVE TECHNIQUE

Nearly all the operations were performed under a minimum cover of spinal anaesthesia. Preliminary cystoscopy was routine to exclude stricture, stone, diverticulum, &c. The transverse suprapubic incision was preferred. In most cases after dissection of the prostate gland and v excision of the bladder neck a no. 4 rubber catheter was led from the prostatic bed through the fundus of the bladder on to the abdominal wall, as described by Adams (1949). With the Harris catheter in situ the small transvesical catheter can be used to maintain a constant drip washout of citrate and later saline solution during the first twenty four hours after operation. Later a similar safeguard against clot retention was achieved by threading a no. 14 F ureteric catheter along the lumen of the Harris catheter, thereby obviating the small transvesical tube.

COMPLICATIONS

The postoperative course was usually smooth, but clot retention, suprapubic leakage, and postoperative incontinence were all encountered.

Of the 60 patients treated by retropubic prostatectomy clot retention occurred in 4. In 2 it was overcome

Further, in all the reported cases of typhoid fever treated with chloramphenicol the organisms continued to be excreted in the feces during treatment although apparently adequate blood-chloramphenicol levels were being maintained. The work of Glazko et al. (1949) may possibly explain this finding. They have shown by chemical methods that 80-92% of the chloramphenicol ingested is excreted in the urine, though only 5% is in a biologically active form. On this evidence, effective concentrations of the antibiotic may not be obtained in the bowel, since only 8-20% of the total dosage is left to be excreted in the feces. The current dosage of chloramphenicol probably produces a sufficient blood-level to kill organisms in the intestinal wall via the blood stream. But organisms that are imbedded in debris and necrotic material, or in the contents of the gut, may be bathed in a solution of chloramphenicol whose concentration is below their sensitivity level so that the more resistant organisms will continue to multiply and may later reinvade the tissue and produce a relapse. The use of an unabsorbable form of chloramphenicol, or its administration in enteric coated capsules as a supplement to the present treatment might therefore be more effective in clearing the intestine of the organisms and might help to prevent relapse and the development of the chronic carrier state.

SUMMARY

In a case of typhoid fever successfully treated with chloramphenicol the initial sensitivity of the infecting organisms ($12 \mu\text{g}$ per mL) was higher than any so far reported.

During a relapse *S. typhi* isolated by blood-culture and from the faeces showed increased resistance to chloramphenicol ($35 \mu\text{g}$ per mL).

A possible explanation for the relapse is put forward and it is suggested that the usual chloramphenicol therapy should be supplemented by the concurrent administration of an unabsorbable form of the antibiotic.

We wish to thank Dr A. W. D. Leishman, under whose care the patient was admitted, for permission to publish, Prof. E. J. Wayne and C. P. Beattie for helpful advice and criticisms, Mr A. S. Foster medical artist of the Royal Infirmary, Sheffield, for preparing the chart, and the technicians of the department of bacteriology, Royal Infirmary, Sheffield.

FLAME PHOTOMETRY

A. G. SPENCER

G.M., M.D. Lond. M.R.C.P.

ASSISTANT, MEDICAL UNIT, UNIVERSITY COLLEGE HOSPITAL
 MEDICAL SCHOOL, LONDON

THE solubility of sodium and potassium salts makes their estimation by chemical means both slow and uncertain so that by the time the results are known they have often lost much of their value. The clinical application of the rapid and accurate methods of flame photometry has therefore proved of great advantage in the diagnosis and treatment of metabolic disorders in medicine, paediatrics, and surgery. Flame photometry determines the concentration of certain metallic elements by the photo electric measurement of the intensity of their characteristic emission spectra, produced when dilute solutions of their salts are sprayed at a constant rate into a standard flame. By this method several determinations can be made in a few minutes with greater accuracy than can be obtained in as many hours by standard chemical techniques.

Balance studies of diabetic acidosis (Atchley et al. 1933), gastro-enteritis in infants (Butler et al. 1933), starvation (Benedict 1915), and the complex biochemical disorders that may follow surgery (Berrv et al. 1948), have led to a better understanding of the gross intracellular deficits of protein, potassium, and phosphate which accompany so many clinical conditions of severe dehydration. Recovery is best aided by the controlled administration of solutions designed to restore simultaneously the acid-base balance, the extracellular losses, and the more easily replaced portion of the intracellular deficits (Butler and Talbot 1944). These three processes of recovery are inseparable. Such treatment requires a more precise knowledge of the total metabolic disorder than can be obtained from single electrolyte estimations on the urine and plasma.

Chloride determinations on the urine are sometimes valuable guides to diagnosis and treatment (Marrott 1947), but they do not necessarily reflect the balance of chloride and sodium in the body. Patients with Addison's disease (Loeb 1932, 1933) or with salt-losing nephritis (Peters and Wakeman 1929) become depleted of extracellular fluid by the uncontrolled loss of water, sodium, and chloride in the urine. Again, when there is excessive catabolism, as in acidosis or following surgical operations, the patient may continue to lose chloride, sodium, phosphate, and potassium in the urine even when seriously depleted of all those electrolytes. Thus, in some metabolic disorders, chloride appears in the urine of salt depleted patients. The opposite phenomenon of low urinary chlorides associated with an excess of salt in the body is widely recognised in established congestive heart failure, but it is also sometimes discovered before failure is apparent. Fatal pulmonary oedema may follow if the low urinary chloride is interpreted as evidence of salt depletion and saline is given intravenously. In the treatment of diarrhoea and vomiting of infancy it is especially important to remember that in very early life the kidneys are unable to form a urine containing a high concentration of chloride (McCance and Young 1941).

Single estimations of electrolytes in the plasma are of limited value, for they do not indicate the balance of electrolytes in the body. This is especially true of the plasma potassium, which may be raised in patients whose cells are depleted of potassium—for example, in untreated diabetic acidosis (Martin and Werkman 1947, Nadler et al. 1948). Furthermore, when dehydration and haemoconcentration are severe, particularly in infancy, high values may be found for the plasma electrolytes, in face of a general bodily deficit.

For the precise diagnosis and controlled treatment of disturbances of the body fluids, a series of electrolyte estimations on the plasma and on all materials entering and leaving the body is essential to determine the biochemical patterns of disorder and recovery. These are the requirements of metabolic research. Experience gained from such detailed metabolic studies is invaluable to the clinician in the biochemical assessment, and more routine treatment of patients when less data are available. It is neither possible nor necessary to make these intensive studies on every patient. But when intracellular losses are to be replaced by the intravenous administration of complex solutions containing potassium, careful electrolyte estimations are highly desirable.

The flame photometer meets this need for rapid and accurate determinations of sodium and potassium. The method has, however, many possible sources of error which may not be widely known. If undetected, these entirely invalidate the results obtained and may cause the instrument to fall into disrepute. Such errors can be avoided if proper precautions are taken in the design and operation of the photometer.

The following account of the principles, construction, and operation of a flame photometer is based on personal

Dosage, temperature, blood levels at various times after doses and sensitivity of organism, showing increasing resistance to chloramphenicol

chloramphenicol was reduced to 3 g daily, and three days later to 1.5 g daily, because the patient had vomited several times.

On March 17 he complained of a sore tongue, and it was red and raw, with some angular cheilosis. Marmite¹ was added to his diet and this condition quickly cleared. By the 18th his diarrhoea had given place to constipation, and glycerin suppositories were required. His clinical condition was now excellent. He had been afebrile for nine days, the physical signs in his chest were resolving satisfactorily, and on March 20 a blood culture was negative though the faeces still grew *S. typhi*.

Chloramphenicol was stopped at 8 P.M. on March 22, though at 6 P.M. the patient's temperature had risen to 101°F. Next day it was 103.4°, and he had mild abdominal discomfort but the only abnormal findings were minimal generalised tenderness and a doubtfully positive Murphy's sign, and his general condition seemed satisfactory. Blood cultures were positive for *S. typhi* on this day and the next (March 23 and 24). Chloramphenicol was therefore restarted on the evening of the 23rd, in doses of 3 g daily, and it was increased to 6 g daily on the 25th after a bacteriological report of the increased resistance of the organism to the drug from 12 to 35 μg per ml had been received. The patient's faeces continued to grow *S. typhi* as they had since admission. His fever settled promptly after the reinstitution of chloramphenicol therapy, and by March 28 he was again afebrile. On this day a specimen of sputum was for the first time sent for laboratory examination, no *S. typhi* was found. There were now no abnormal physical signs in the chest or abdomen, and the chloramphenicol was reduced to 4 g daily, and seven days later to 3.5 g daily and continued in this dose until April 11 (fifteen days after the relapse) when it was discontinued.

S. typhi was present in the faeces until April 6 (the fifty second day of disease), when in spite of its increased drug resistance (see below) the organism disappeared from the stools and remained absent from eight successive daily specimens. The patient was now convalescent. He felt well, and radiography of his chest on April 24 showed complete

resolution of the pneumonic lesion. He was discharged from hospital on April 27.

BACTERIOLOGY

Methods—The *S. typhi* isolated by blood culture was sent to Dr A. Felix, F.R.S., of the Central Enteric Reference Laboratory and Bureau, who reported that the organism belonged to an untypable V₁ strain.

The sensitivity of the various cultures was estimated by inoculating dilutions of standard chloramphenicol in phenol red glucose serum water (May et al 1947) with the organism under test. The chloramphenicol assays were made by comparing serial dilutions of the test serum and of standard chloramphenicol in the above mentioned medium inoculated with *B. cereus* (Lederle no 5).

In the Widal tests the *S. typhi* H antibody was estimated by Dreyer's technique, the *S. typhi* O by the Felix technique, and the *S. typhi* V₁ by the technique recommended by the Standards Laboratory, Colindale.

Progress—During the first thirty days of the man's illness a heavy growth of *S. typhi* was obtained from his faeces even by direct plating on MacConkey's medium. On the thirty-sixth day, a moderate growth of the infecting organism was obtained by the use of desoxycholate medium. From the thirty-ninth day, *S. typhi* was isolated only with the aid of 'Selenite F' medium, and the faeces yielded very few colonies on the last three occasions when the organism was isolated.

DISCUSSION

The case reported here is interesting from several points of view and raises further problems in the chloramphenicol treatment of typhoid fever.

In the first place, the organism isolated before treatment was sensitive to 12 μg and resistant to 10 μg per ml—a much higher resistance than any yet reported, so far as we can determine. Thus Edge (1950) found that all the tested organisms in his cases were sensitive to 2.5 μg and resistant to 1.5 μg per ml. Secondly, increased resistance to chloramphenicol was first shown, by the organism isolated from the faeces on March 14—nine days before the relapse. When the relapse occurred the patient was virtually still under treatment, since chloramphenicol was stopped for less than twenty-four hours, and indeed the man's temperature started to rise two hours before the last dose was given. Further, positive blood cultures were obtained from samples collected on the second and third days of the relapse. The second of these samples contained 12 μg of chloramphenicol per ml, and the resistance of the organisms isolated from these two cultures had increased to 35 μg per ml.

In the published reports on the treatment of typhoid fever with chloramphenicol there has been no suggestion that drug resistance played any part in the failure of treatment or in the occurrence of relapses. Yet the present case suggests that some relapses may be due to acquired resistance, and that strains of *S. typhi* may be encountered which require very large doses of chloramphenicol for successful treatment. Hence in our view, the sensitivity of the organism and the serum chloramphenicol level should be estimated in every case as a guide to dosage, and where this is impracticable the dosage should be that calculated to produce a serum level of not less than 50 μg per ml—i.e., 4–6 g daily.

Chronic typhoid carrier states following chloramphenicol therapy have recently been reported (Douglas 1950, Good and Mackenzie 1950). In view of the increased resistance of the organism in our case, it seems that patients who become chronic typhoid carriers after chloramphenicol treatment may be excreting an organism with a greatly heightened resistance to the drug.

when the pressure is 15 lb per sq in. The rate of atomisation is largely governed by the air pressure, which is readily controlled. Some types of atomiser with gravity or capillary feeds produce coarse droplets at very inconstant rates (fig 2). The compressed air, which must be free of oil and dust, is delivered to the atomiser through an adjustable constant-pressure valve connected to a pressure gauge registering from 0 to 20 lb per sq in.

The spray passes directly into a glass or plastic chamber (sc in fig 3b), designed to eliminate any coarse droplets, which condense and leave the instrument through the constant-pressure trap (T). The compressed air, now containing only very fine droplets, passes from the spray chamber through a short wide tube into a narrow metal preheating cylinder (SC2) which surrounds the burner (B). It is essential that the spray should enter this cylinder tangentially and at a level above the air holes in the burner, otherwise the flame will be blown out.

A flame supplying a constant amount of energy is obtained by using a large Fisher-type burner, with

adjustable gas-jet and a fine mesh nickel grid. The supply of gas is controlled in the same way as the compressed air. As a rule coal gas, at a pressure of 7 cm of water, is used, but butane or acetylene (pressure 7 lb per sq in.) may be used with the appropriate burners. Coal gas is satisfactory for the estimation of sodium and potassium, provided that it burns with a colourless flame and the mains pressure is high and relatively constant. The flame is protected from cold air by two concentric metal chimneys (IC and EC) and by a larger asbestos fire box (AB). Narrow windows permit light from the central zone of the flame to pass out into the optical systems, but exclude light from the top, base, and edges of the flame. This system of flame protection and ventilation keeps the flame hot and steady and the rest of the photometer cool. This cooling effect is important because the output from selenium photo electric cells varies widely with temperature changes. In this instrument a dial thermometer monitoring the air immediately around the photocells records temperature variations which are consistently less than 2°C. If temperature control is less precise, an electric heater with thermostatic control should be installed.

The double optical systems of mirrors (M in fig 3), condensing lenses (L), and filters (F) are arranged to focus light of selected wave length on to the photocells. Final adjustment is determined by trial to obtain the maximum galvanometer deflection with a given test

Fig 4—Relation of emission spectra to transmission of filters

solution. The whole of the optical system must be light tight and coated internally with jet-black paint.

Combinations of thick glass filters select the regions of the spectrum emitted by sodium, potassium, and lithium. Along one optical path the filters for lithium are kept constant. On the other side the filters for sodium and for potassium are mounted on a drum (RFH), which is turned to select the required filter combination. An iris diaphragm is incorporated along the light path for sodium. To exclude sodium light from the photocells when potassium or lithium spectra are to be measured, a special interference or cut out filter is used. It is essential to make detailed spectro-photometric tests on the completed instrument to ensure that the spectrum given by any one element is completely removed by the filters used during estimations of the other elements. This requirement is met in the photometer described, except that calcium emits a number of bands which are passed to a small extent by the filters used in estimating sodium (fig 4). The resulting error is so small that it can only be detected when the concentration of calcium in the solution under test is more than ten times that of sodium. Interference filters provide a very precise method of spectral selection and also have the advantage of transmitting more light

experience with an instrument that has given reliable service in several thousand determinations, on published work (Gerlach 1925, Lundegårdh 1929, 1934, Berry et al 1946), and on discussions with other workers in this field

PRINCIPLES

The physical basis of flame photometry is complex, but a brief study of the main principles will suffice for practical purposes

When an atom is heated one of its electrons absorbs the added energy and jumps to an outer orbit, where it rotates at a higher energy level. This electron is now in an unstable position and tends to spring back to the orbit from which it came. As it returns, it emits as light the difference in energy required for rotation in the two orbits concerned. The intensity and wave length of the light is related to the position and energy level of the moving electron. Hence, each element, when heated in a flame under standard conditions, emits a characteristic light spectrum not given by any other element.

However, when energy is supplied at greatly different rates—i.e., at widely different temperatures—one element may produce a series of different emission spectra according to the number of orbiting electrons available in its atoms to absorb the energy supplied. At very high temperatures the outer electron may leave the field of the nucleus altogether, and an additional or ion spectrum will then be produced. Thus, the higher the temperature the more complex the spectra become. In the hydrogen air flame only the most easily excited spectral lines—the first atomic spectra of the alkali and the alkaline earth metals—are produced. The flame must be sufficiently hot to vaporise the compounds to be analysed. In the solid phase, continuous or band spectra are produced which are useless for analytical purposes.

At high temperatures interference phenomena occur between spectra of different elements. For example, with an oxyacetylene flame at 3500°C the presence of sodium increases the apparent intensity of the characteristic potassium emission. This effect is minimal at 1800°C in the hydrogen air flame.

An emission spectrum may to some extent be absorbed by atoms of another element, and well-marked specific absorption occurs when unheated atoms of the same

element are present. Both these effects are minimised by dilution. But in flame photometry the flame must supply energy at a sufficient rate to excite all the atoms delivered to it. Otherwise, the non radiating atoms will immediately absorb the light emitted by those that have been excited.

The main conditions for quantitative flame photometry may be summarised as follows. A solution of the test material, appropriately diluted, is delivered at a uniform rate to a flame of constant energy output. After vaporisation a variable number of atoms will thus be excited, and each atom will emit a constant amount of light of a characteristic wave length. This light is concentrated and selected by a suitable optical system, converted into electrical energy by a photocell, and measured by a galvanometer.

In *direct flame photometry* a single optical system and one photo electric cell are used, so that the deflection of the galvanometer is a measure of the intensity of the emission spectra and of the concentration of the elements in the heated specimen.

In *internal standard flame photometry* a constant proportion of lithium is added to all the test and standard solutions. By the use of a double optical system and matched photo electric cells the ratio of two different spectra is measured under conditions such that any uncontrolled variation in the emission of one element is balanced by a similar alteration in that of the lithium internal standard element. It will be shown later that this internal standard technique compensates for many of the serious errors which limit the value of direct flame photometry in the analysis of complex biological fluids.

How these principles are applied to the design and operation of a combined direct and internal standard photometer is described below. The diagrams (figs 1-3) are drawn to scale, so that the dimensions of the apparatus, none of which is critical, may be obtained by measurement.

CONSTRUCTION OF THE PHOTOMETER

Emission spectra are produced by spraying into the flame an "atomised" aqueous solution of the materials to be examined. The heat rapidly evaporates the minute droplets of water and vaporises the compounds in solution. These are now in a gaseous phase so that characteristic emission spectra are produced.

The design of the atomiser is one of the most important considerations in the construction of a photometer. The rate of atomisation must be constant and the droplet size uniformly small. The atomiser must be easy to clean. In the best type a concentric flow of fluid and air produces a conical mist of nearly uniform particle size, and 10-15 ml of the test solution is atomised per minute, using 8 litres of compressed air.

Fig 2—Three types of atomiser with (A) capillary feed; (B) gravity feed; and (C) feed controlled by air pressure

than combinations of glass filters * Spectral selection by means of a diffraction grating or a prism and slit mechanism requires a much higher degree of precision than can be obtained in the average workshop

Large selenium barrier layer photo electric cells of matched output have been used in this instrument because they have a broad spectral response, are free from drift and fatigue, and have a relatively high output at low intensities of illumination Most selenium cells are not sensitive to light of a wave length longer than 650 m μ and are therefore useless for measuring the emission spectra of lithium and potassium It is possible to obtain red sensitive photocells, and for photometry those with the largest output at 770 m μ should be chosen The output of the cells should be such that, with the instrument switched to the direct circuit, a solution containing 0.5 m eq of potassium per litre will produce a full scale deflection of the galvanometer A biased circuit may be used when very low light intensities are encountered

Phototubes may be used in place of the selenium cells, but these require a long warming up period before

of air (15 lb per sq in) and gas (5 cm of water) are adjusted to give a steady sub blast type of flame The selector dial is turned to provide the appropriate filters Distilled water is poured into the atomiser funnel and the galvanometer is adjusted to zero The solution to be tested is now poured in and the sensitivity dial is turned until a suitable galvanometer reading is produced Readings are obtained for two standard solutions (all standard solutions must be kept in hard glass bottles) of the same element, one slightly more concentrated and the other slightly more dilute than the unknown solution By interpolation between these two standard readings the concentration of the unknown solution is obtained By using four or more standards a calibration curve can be constructed, and with solutions up to 0.5 m eq per litre this should be linear Above this concentration the galvanometer reading will not be directly proportional to the concentration, because specific absorption by non radiating atoms of the same element occurs in the flame If a calibration curve is used, it is essential to construct a new one for each

series of estimations and to check the readings repeatedly during the series of observations

With simple dilute solutions (less than 1 m eq per litre) the accuracy of the estimations obtained is $\pm 3\%$ However, small variations in the pressures of gas or air will produce a very large error (figs 6 and 7) Furthermore, the viscosity of the test solutions modifies their rate of atomisation and hence the galvanometer readings obtained (fig 8), with many biological fluids—e.g., plasma diluted less than 1 in 50—a correction for viscosity is therefore essential In complex solutions non specific absorption by other elements is pronounced. The presence of organic molecules, such as urea, in the solutions also

interferes with estimations (fig 9), and some acids (e.g., nitric acid, fig 10) strongly inhibit spectral emission Thus the many possible sources of error make direct flame photometry a very uncertain method of analysing biological fluids Fortunately, many of these difficulties can be overcome by internal standard flame photometry (Berry et al 1946)

Internal Standard Flame Photometry

Lithium is the most suitable element for the internal standard because it seldom occurs in biological fluids, it is closely related to sodium and potassium, and it gives an intense line spectrum midway between these two elements A constant proportion of lithium (1 in 20,000) is added to all the standard solutions and to those of

FIGS 6 AND 7—Effect of variations in gas-pressure and air-pressure on accuracy of direct and indirect flame photometry

use Their output is comparatively low, so they require a stable form of amplification Photomultiplier tubes may be used, but these require a well regulated electric power supply and also take a considerable time to reach a stable output

The electrical circuit shown in fig 5 is designed for use with selenium cells The two pole double throw switches enable the instrument to be used either as a direct or as an internal standard instrument The wire wound linear rheostats allow different voltages to be tapped off the cells, and thus act as fine and coarse sensitivity selectors When used on the internal standard circuit the photocells oppose each other, and a balance or null point reading is obtained by turning the potentiometer dial until the galvanometer is steady at zero

A highly sensitive galvanometer is essential The one here has a sensitivity of 0.0005 microamps per mm, a period of 4 sec, an internal resistance of 4000 ohms, and a critical external damping resistance of 50,000 ohms A galvanometer shorting switch should be incorporated in the circuit

OPERATIONAL INSTRUCTIONS

Direct Flame Photometry

To ensure a stable zero, the galvanometer is switched on 10 minutes before use The gas is lit and the pressures

FIGS 8 AND 9—Effect of changes in viscosity of test solution and presence of urea on accuracy of direct and indirect photometry

* Since this paper was written interference filters with a transmission band width of less than 10 m μ have become available and these are now in use

unknown concentration that are to be tested. The potential produced by the selected lithium light falling on one photocell is opposed by a similar potential from the opposite cell, which is excited by the sodium or the potassium light. These E.M.F.s are balanced by an accurate potentiometer, and a calibration curve is constructed by plotting the potentiometer readings against the concentration of the standard solutions.

Many of the non-specific sources of error which interfere so greatly with direct flame photometry equally affect the emission of the lithium and of the sodium or potassium spectra. Such effects will now be opposed by the balance technique and largely cancel out. It can be seen from figs 6-10 that the device of an internal standard compensates for any small variations in the pressures of gas or air (figs 6 and 7), for changes in viscosity of the test solutions (fig 8), for the effects of some organic molecules (fig 9), and for the absorption caused even by dilute solutions of nitric acid (fig 10).

This method does not eliminate all possible sources of error. Solutions of carbohydrates emit a continuous band spectrum of carbon, which gives falsely high readings for sodium. In estimating the sodium content of solutions containing sugar in concentrations over 0.01% the carbohydrate must always be oxidised completely before testing. Studies on the effect of

protein in the test solutions have been made by the use of albumin rendered almost electrolyte-free by electro-dialysis. Albumin in concentration of less than 0.05% has a negligible effect on internal standard flame photometry. Hence it is possible to estimate sodium and potassium in

Fig 11—Calibration curves for indirect flame photometry over wide range of sensitivities.

plasma without previous precipitation of the proteins, provided the plasma is diluted by the addition of 100 or more parts of water. Urine, if suitably diluted, can be analysed directly, but with tissues, diets, and stools complete oxidation of organic matter by boiling with concentrated HNO_3 is an essential preliminary step.

With suitably prepared solutions the accuracy of sodium and potassium estimations by the internal standard technique is within $\pm 1.5\%$, over a concentration range of 0.01-1.0 m eq per litre (fig 11). New developments are under trial by means of which calcium and other elements may be estimated, even in the presence of a large excess of sodium.

Although the techniques described provide simple, accurate, and rapid means of estimating sodium and

potassium in complex biological fluids, it is absolutely essential for the operator to have a sound knowledge of the theoretical principles if he is to avoid the many practical difficulties. In every new application of flame photometry it is wise to check the initial results against those obtained by standard chemical methods.

SUMMARY

The principles, design, and operation of a combined direct and internal standard flame photometer are described.

Some of the many possible sources of error in flame photometry are discussed together with the methods for avoiding them.

Flame photometry is an accurate and rapid technique for estimating the concentration of sodium and potassium in aqueous solutions or in plasma or other complex biological fluids, and is a great convenience in clinical medicine, paediatrics, and surgery. Despite the apparent simplicity of the method it is unsuitable for the use of unskilled or uncritical workers.

The work described in this paper was done during the tenure of a Bilton Pollard Fellowship from University College Hospital and a Research Fellowship at the College of Physicians and Surgeons, New York.

I wish to express my thanks to Prof M L Rosephelm for his help in the preparation of this paper to Prof Robert F Loeb, of the College of Physicians and Surgeons, New York, for his encouragement and financial aid, and Dr G H Mudge and Dr C L Fox for their ready advice and assistance.

Reviews of Books

Atlas of Mahfouz's Obstetric and Gynaecological Museum

NAQUIB PACHA MAHFOUZ M.Ch., F.R.C.O.G. (Hon.), F.R.C.P. F.R.C.S. (Hon.), consultant obstetric and gynaecological surgeon, Kasr-el-Amy Hospital, consulting surgeon, Kitcheners Memorial Hospital, director of the Gynaecological Department of the Coptic Hospital, Altrincham, England. John Sherratt & Son 1949. Pp about 1250. Set of 3 vols, £9 9s.

This atlas is an illustrated catalogue of mounted pathological specimens in the Mahfouz Obstetric and Gynaecological Museum in Cairo. The museum, containing almost 1300 specimens, is the work of Mahfouz Pasha, who operated on most of the cases himself. In the preface he says: "In passing from one stage to another I have given a description of the pathological anatomy of the parts concerned. In subjects of which I have made special studies I have described the clinical features and the operative procedures I perform and have given an historical review showing the evolutions which gradually developed into our present-day conception of these diseases." He hopes that the atlas will prove useful to advanced students who propose to specialise in gynaecology and obstetrics and who are already familiar with ordinary textbooks.

The strength of the book lies in its wealth of material, especially concerning such conditions as rupture of the uterus, chorionepithelioma, and concealed accidental

than combinations of glass filters * Spectral selection by means of a diffraction grating or a prism and slit mechanism requires a much higher degree of precision than can be obtained in the average workshop

Large selenium barrier layer photo electric cells of matched output have been used in this instrument because they have a broad spectral response, are free from drift and fatigue, and have a relatively high output at low intensities of illumination Most selenium cells are not sensitive to light of a wavelength longer than 650 m μ and are therefore useless for measuring the emission spectra of lithium and potassium It is possible to obtain red sensitive photocells, and for photometry those with the largest output at 770 m μ should be chosen The output of the cells should be such that, with the instrument switched to the direct circuit, a solution containing 0.5 m eq of potassium per litre will produce a full scale deflection of the galvanometer A biased circuit may be used when very low light intensities are encountered

THE LANCET

LONDON SATURDAY, NOV 25, 1950

Balances

THE Ministry of Health's decision to reduce the number of registrars prompts three questions. Is this necessary? Is it fair? And can the hospitals still be run efficiently?

If future registrars, having finished their training, are really to have a reasonable chance of a consultant post, then a cut of some sort is inevitable for even if the consultant services were considerably expanded the present numbers would be too great. We have all hoped for such expansion, and with unlimited resources of money the arguments for undertaking it would be irresistible. But the resources of the health service are very far from being unlimited, they are, in fact, not much more than sufficient for maintenance. Last March Sir STAFFORD CRIPPS, as Chancellor of the Exchequer, declared in the plainest terms that the nation was spending as much as it could afford on its health service, we could not, he declared, exceed the present rate of expenditure. Moreover, in this as in other countries, the cost of providing medical care and especially hospital care is rising year by year. Thus if the present restriction on spending is retained—and the inflationary pressure of rearmament makes it virtually certain it will be—we may soon be thinking, not of where the service should be expanded, but of where it can least harmfully be contracted. Economies are of course possible, but it is broadly true that no part of the service can now be substantially developed except by with drawing money from some other part. Repeatedly this journal has urged that the right policy for the next few years is to concentrate especially on improving the kind of medical care that can properly be given outside hospital, and for this purpose to improve the conditions of general practice. Facing the economic facts, we cannot simultaneously join in the demand that consultant establishments should now be increased. Indeed, if no personal hardships were involved, we should not be sorry to see the body of general practitioners strengthened by many able men and women, some of whom are good general doctors as well as good specialists. We should not be sorry, that is to say, if we thought that the conditions of practice would permit them to do good work.

Unfortunately, as things stand, very real hardship is in prospect for hundreds of registrars, no longer in their first youth, who will now have to make a fresh start. Many of them recognised from the first that they risked more than their predecessors in similar posts, and this awareness has gradually become more acute, for example, last year, at the opening meeting of the B.M.A. registrars' group, members heard it suggested that only 1 in 5 of senior registrars would gain a consultant appointment. Yet by usage the registrar should have a fair chance of advancement, which is now to be denied him. Here

the profession itself bears some responsibility, for restraint in claims for registrars, together with professional advice to hospital authorities, might have helped to keep the numbers within bounds, and the vigour with which the cuts have been denounced might equally have been applied to inhibiting the earlier heedless growth. Where the Ministry of Health has been at fault is in failing to give its facts sooner and to secure agreement on what should be done. A year ago we remarked that registrars had too long been kept in the dark about their prospects, and we called on the regional boards to furnish what illumination they could. The boards, we understand, were asked some time ago to review establishments in order to restore some sort of balance, but most of them preferred to leave the initiative to the Ministry itself. The reduction, now that it is on us, is startling more for its abruptness than its extent.

This abruptness is likely to handicap most severely the former municipal hospitals, some of which have gained immensely from having registrars added to their medical complement, and the regional reviewing committees will have to ensure that the claims of these hospitals (provided they are compatible with proper training) are not overshadowed by those of teaching hospitals. The expert clinical assistants on whom the Ministry seems to rely to fill the gap are unlikely to be found where they are wanted and as soon as they are wanted, and as Dr BARNARD notes in his letter on another page, these assistants, even when they are appointed, may not live near enough to the hospital to give all the help of which they are capable. There is a further and very serious difficulty which will not take shape until the regional reviews are completed in the New Year. The Ministry's intention is apparently to relate registrarships in each subject to the probable openings, and if this policy is carried through the number of registrars allowed to continue in such popular subjects as general surgery will be far below the number implied by the over-all reduction already announced. General surgery is one of the subjects in which the registrar may be giving indispensable help, and in this, and possibly other, subjects the proposed balancing of registrar numbers against probable consultant vacancies may cause serious loss of efficiency which can only partly be warded off by the extension for one year of the tenure of senior registrars. Indeed, while the new restricted establishment, equated to consultant vacancies, is likely to provide a fair deal for the next generation, it will be unfairly small for the hospital service, for three different reasons.

- 1 The number of consultants having steadily increased during the past two or three decades, the number of vacancies per annum (to which the number of registrars is to be related) is less than the number of consultants divided by the average number of years they work. In other words, because thirty years ago fewer consultants were appointed, there are now fewer vacancies than the present total might suggest.

- 2 The upper age-limit in the health service has been set at sixty five, and in many places this has had the effect of extending for five years the working life of those who would otherwise have retired. This again keeps down meanwhile the number of vacancies.

- 3 Some consultants who have passed the age of sixty-five are still doing valuable work in the hospitals.

hæmorrhage The case histories are clear, concise, and instructive, and the discussions on such subjects as rupture of the uterus are most interesting. In dealing with the management of fibroids complicating pregnancy the value of conservative treatment is emphasised (In a country like Egypt, where the patient still hesitates to consult a doctor, or sometimes to take his advice, there is an opportunity to demonstrate what can be accomplished by "masterly inactivity." In some parts of Britain, where many of these serious complications are now seldom seen, there may be a tendency to over-treat those which do occur.) On the other hand there are surprisingly few specimens illustrating eclamptic toxæmia, and those which do appear are not entirely satisfactory. Throughout the book the paintings are technically excellent, and many of the drawings are very good, but they suffer from the fact that they depict the appearance seen in the jar at the time they were painted or drawn and not the appearance seen at the time of operation when the specimens were obtained. The result is that the paintings are not life like and some of the drawings are difficult to follow because the specimen has become wrinkled. This is a great pity in view of the great variety of unusual cases available. Some of the photomicrographs are likewise disappointing, the histological detail being poor and the fields not always well chosen.

Though the author says that this book is for advanced students, much of the more systematic discussion is elementary and rather out of date. For example, he states that "the most common cause of foetal death is intoxication through the maternal circulation. This may be of bacterial origin such as syphilis, malaria, auto infection, etc., or due to metabolic disease such as diabetes or albuminuria or to the toxæmia of pregnancy. Syphilis is by far the most important antenatal disease which leads to death of the foetus." The general effect of this unevenness in the standard of writing is that the really important cases and the instructive discussions are hidden away in the systematic text and among statistics which by their very nature cannot be very helpful.

Any such book is open to criticisms, and if this monumental work has shortcomings they must not be allowed to obscure its real value. It consists of three volumes printed on fine paper and illustrating conditions which in this country the obstetrician seldom sees. Dr Mahfouz is to be congratulated on bringing so great a labour to a worthy conclusion.

John Hunter

S. ROODHOUSE GLOYNE, consulting pathologist, London Chest Hospital and King Edward VII Sanatorium, Midhurst, Edinburgh. E & S Livingstone 1950. Pp 104. 15s.

IN little compass the late Dr Gloyne has contributed a notable study of a much studied man. He draws what one feels must be a true picture of Hunter's strange character—a man of rough (even coarse) fibre, with little book-learning, with much to say yet little able to express his thoughts, but a man moved by a passionate desire to understand facts and with an intellect which many times led him straight to the truth. It is the peculiar value of this book that it places John Hunter's figure against a vividly painted background of the London life of his time—on one side indescribable squalor, on the other gaiety and fashion moving in sedan chairs to the opera or Vauxhall. The teacher of anatomy and surgery was more often in contact with the squalor than with the refinement of the 18th century. While John Hunter's charming wife could enjoy the friendship of Mrs Montague and of Fanny Burney, her husband was forced by circumstance to take part in the unsavoury transactions of the resurrection men. The stench of the crowded dissecting rooms, housed in makeshift cellars or outhouses, was such that dissection became a seasonal occupation, impossible and abandoned in the heat of summer.

The book is without explanatory footnotes, and there are no detailed references given to quotations from other works. But as it stands, both in style and in matter, it is a little masterpiece of medical biography.

Coronary Circulation in Health and Diseases

DONALD E. GREGG, M.D., chief research physician, medical department, Field Research Laboratory, Fort Knox, Kentucky. London: Henry Kimpton 1950. Pp 227. 31s. 6d.

Dr Gregg, approaching his subject as a laboratory and research worker, deals most fully with coronary flow in animals, first under basal conditions as nearly physiological as possible, and then under the influence of various factors which determine alterations in flow. It seems doubtful, from the observations discussed, whether there is any evidence of direct nervous control of the coronary calibre, or of the influence of drugs (the nitrites excepted), for both nerves and drugs affect the work of the myocardium, with metabolic consequences which closely control the coronary circulation. The last chapter deals with the histology of coronary lesions, the methods by which they may be produced experimentally, and their effects. Abnormal lipid metabolism is not thought to be a factor in most cases of coronary obstruction, the various drugs used with the object of preventing ventricular fibrillation are probably ineffective, and the possibility that any drug can limit the size of an infarct in man seems to be remote. Dr Gregg has repeatedly to conclude that the views and statements of others are unwarranted or unproved. The result is a review in which the reader can feel confidence even if it lessens his hope of improving coronary blood-flow with most of the drugs proposed for the purpose.

Progress in Chromatography, 1938-47

L. ZECHMEISTER, California Institute of Technology, Pasadena, California. London: Chapman and Hall, 1950. Pp 307. 45s.

THE ten years covered by Professor Zechmeister's review have seen much new invention and adaptation in the field of chromatography. Partition chromatography, preparative and analytical, in columns or on paper strips, has been known for only a few years, but these methods are now at least as important as the original adsorption technique.

After a general section devoted to principles and methods, the author has provided a compendium of actual experimental detail, dealing with chlorophyll, porphyrins, bile pigments, carotenoids, miscellaneous natural pigments, synthetic dyestuffs, miscellaneous aliphatic substances, lipoids, carbohydrates, amino acids and peptides, sterols and some terpenes, and some related compounds, benzene, naphthalene, diphenyl, diphenyl alkyl and the indene series, heterocyclic compounds, alkaloids, vitamins, antibiotics, enzymes, and miscellaneous biological substances. He also discusses inorganic chromatography, and the applications of chromatography to technology.

Ten years is too long to wait to review this rapidly expanding field, and we hope that Professor Zechmeister will repeat this signal service in five years' time.

Essays in the History of Medicine

GEORGE GASK, C.M.G., D.S.O., F.R.C.S. London: Butterworth 1950. Pp 209. 30s.

THIS volume of eight essays will be welcomed by all students of medical history. Every one of them has something new to say and every one shows evidence of careful research.

For instance John Hunter's experiences as an army surgeon in Portugal, recounted in the sixth essay, are probably little known even to those who know much of the history of his later life. It is interesting to find that, a hundred years before Florence Nightingale astonished the world, the hospital with 202 patients in which he served was equipped with a regular establishment of women nurses, including a matron, 2 head nurses, and 18 nurses—1 nurse to every 10 patients. Nothing is to be learnt of the training of these women, but on Aug. 9, 1762 the Adjutant-General wrote to the Commander in Chief that it would be unwise to discharge any of the nursing staff "as their places cannot be supplied in an emergency." This suggests that they possessed some skill which could not be replaced by untrained women hurriedly impressed. Professor Gask thinks it likely that they were recruited from the London hospitals. Things seem to have been better not only after, but also before, the Crimea.

THE LANCET

LONDON SATURDAY, NOV 25, 1950

Balances

THE Ministry of Health's decision to reduce the number of registrars prompts three questions. Is this necessary? Is it fair? And can the hospitals still be run efficiently?

If future registrars, having finished their training, are really to have a reasonable chance of a consultant post, then a cut of some sort is inevitable for even if the consultant services were considerably expanded the present numbers would be too great. We have all hoped for such expansion, and with unlimited resources of money the arguments for undertaking it would be irresistible. But the resources of the health service are very far from being unlimited, they are, in fact, not much more than sufficient for maintenance. Last March Sir STAFFORD CRIPPS, as Chancellor of the Exchequer, declared in the plainest terms that the nation was spending as much as it could afford on its health service, we could not, he declared, exceed the present rate of expenditure. Moreover, in this as in other countries, the cost of providing medical care and especially hospital care is rising year by year. Thus if the present restriction on spending is retained—and the inflationary pressure of rearmament makes it virtually certain it will be—we may soon be thinking, not of where the service should be expanded, but of where it can least harmfully be contracted. Economies are of course possible, but it is broadly true that no part of the service can now be substantially developed except by withdrawing money from some other part. Repeatedly this journal has urged that the right policy for the next few years is to concentrate especially on improving the kind of medical care that can properly be given outside hospital, and for this purpose to improve the conditions of general practice. Facing the economic facts, we cannot simultaneously join in the demand that consultant establishments should now be increased. Indeed, if no personal hardships were involved, we should not be sorry to see the body of general practitioners strengthened by many able men and women, some of whom are good general doctors as well as good specialists. We should not be sorry, that is to say, if we thought that the conditions of practice would permit them to do good work.

Unfortunately, as things stand, very real hardship is in prospect for hundreds of registrars, no longer in their first youth, who will now have to make a fresh start. Many of them recognised from the first that they risked more than their predecessors in similar posts, and this awareness has gradually become more acute, for example, last year, at the opening meeting of the B.M.A. registrars' group, members heard it suggested that only 1 in 5 of senior registrars would gain a consultant appointment. Yet by usage the registrar should have a fair chance of advancement, which is now to be denied him. Here

the profession itself bears some responsibility, for restraint in claims for registrars, together with professional advice to hospital authorities, might have helped to keep the numbers within bounds, and the vigour with which the cuts have been denounced might equally have been applied to inhibiting the earlier heedless growth. Where the Ministry of Health has been at fault is in failing to give its facts sooner and to secure agreement on what should be done. A year ago we remarked that registrars had too long been kept in the dark about their prospects, and we called on the regional boards to furnish what illumination they could. The boards, we understand, were asked some time ago to review establishments in order to restore some sort of balance, but most of them preferred to leave the initiative to the Ministry itself. The reduction, now that it is on us, is startling more for its abruptness than its extent.

This abruptness is likely to handicap most severely the former municipal hospitals, some of which have gained immensely from having registrars added to their medical complement, and the regional reviewing committees will have to ensure that the claims of these hospitals (provided they are compatible with proper training) are not overshadowed by those of teaching hospitals. General surgery is one of the subjects in which the registrar may be giving indispensable help, and in this, and possibly other, subjects the proposed balancing of registrar numbers against probable consultant vacancies may cause serious loss of efficiency which can only partly be warded off by the extension for one year of the tenure of senior registrars. Indeed, while the new restricted establishment, equated to consultant vacancies, is likely to provide a fair deal for the next generation, it will be unfairly small for the hospital service, for three different reasons.

- 1 The number of consultants having steadily increased during the past two or three decades, the number of vacancies per annum (to which the number of registrars is to be related) is less than the number of consultants divided by the average number of years they work. In other words, because thirty years ago fewer consultants were appointed there are now fewer vacancies than the present total might suggest.

- 2 The upper age-limit in the health service has been set at sixty-five, and in many places this has had the effect of extending for five years the working life of those who would otherwise have retired. This again keeps down meanwhile the number of vacancies.

- 3 Some consultants who have passed the age of sixty-five are still doing valuable work in the hospitals.

The conclusion is inescapable that, unless many recently upgraded hospitals are to be deliberately downgraded, some of their specialised work will have to be done by doctors who have no further expectation of becoming consultants. Ways have to be found by which it can be done well and willingly, and by which the transit of many hospital registrars into general practice can be made at least tolerable. The need here is for constructive suggestions, and we welcome those put forward by Dr TALBOT ROGERS on p 641.

Q Fever

THOUGH it may be one of the rarer infectious diseases, Q fever is attracting world-wide attention, partly because of its remarkable and varied epidemiology and partly because of the unorthodox character of the causative organism, *Rickettsia burnetii*.

Clinically it has few striking characteristics, and it must be sought among patients with "pyrexia of undetermined origin" or with "primary atypical pneumonia". Generally the illness begins abruptly with a particularly severe headache, sometimes accompanied by photophobia. The headache may indeed be so intense that meningitis is suspected, but a spinal tap rarely reveals an increase of cells in the cerebrospinal fluid. There is high fever, and profuse sweating as the temperature fluctuates from 103-4°F to normal during the course of a day or less. "Burning eyes," lacrimation, and conjunctivitis may add to the patient's discomfort, but he has none of the upper respiratory symptoms of "influenza" or "febrile catarrh". The illness lasts on the average some twelve days, the temperature falling by lysis. Between the third and sixth days, or thereabouts, there may be a little cough, and on careful examination a few fine râles will be heard in the chest, but the signs are slight in relation to the extent of the lung lesion revealed by X rays. Pneumonia is present in about 70-80% of patients, including some of those with a very mild general illness, in fact in one large outbreak¹ radiography was used for discovering cases. But Q fever is more than an infection of the lung. *R. burnetii* can be recovered from the blood stream during the fever and from the urine during early convalescence, and consequently lesions may be spread widely. MOESCHLIN and KOSZEWSKI,² in 50 cases with serologically proven Q fever, reported 9 with complications (5 thrombophlebitis with pulmonary embolism, 3 epididymitis, 1 encephalitis, and 1 pancreatitis). All these extrapulmonary complications appeared after the fourteenth day of illness, when the lung lesion was resolving. The findings of WHITTICK,³ who in a fatal case demonstrated rickettsiae in the lung, spleen, brain, testis, and kidney, suggest that the lesions outside the lungs are probably due to the rickettsia itself. This occurrence does much to modify an impression, gained largely from studies of the disease in young and healthy troops, that Q fever is necessarily benign and trivial. Convalescence is often marked by loss of weight, muscular pains, lassitude, and easy fatigability which can last three

months or longer. In some patients this vague disability is punctuated by a genuine relapse with fever and a return of the original symptoms, and a few have had relapses occasionally for years.⁴

A tentative diagnosis of Q fever can be confirmed by isolating the organism or by demonstrating the highly specific complement-fixing antibodies which appear in the serum during convalescence. In this country the Virus Reference Laboratory of the Public Health Laboratory Service, examining sera from some 700 patients with acute infective respiratory disease, found that about 3% had a significant titre to *R. burnetii*.⁵ Of the 300 patients clinically diagnosed as having "atypical or virus pneumonia," there was serological evidence of infection with influenza virus in 16%, with a virus of the psittacosis ornithosis group in 2%, and with *R. burnetii* in 5%, while 11% had either cold hæmagglutinins, *Streptococcus MG* agglutinins,⁶ or both. Cold and *Strep MG* agglutinins were rarely observed in association with a positive specific complement fixation test for influenza, psittacosis ornithosis, or *R. burnetii*. It seems, therefore, first that *R. burnetii* is not a common cause of atypical pneumonia in Great Britain, and secondly that the likelihood of any particular case of atypical pneumonia being one of Q fever is small if the patient has a positive cold hæmagglutinin or *Strep MG* agglutinin test.

Cases of Q fever have now been found in Kent, Devon, Somerset, Gloucestershire, Wiltshire, Denbighshire, and Oxfordshire. Papers in our columns have described the detection of the first cases,⁷ the clinical features of the cases,⁸ and the isolation⁹ of *R. burnetii* from one of the patients, and a few months ago we reviewed the epidemiology of the disease.¹⁰ This week we publish communications on the properties of some English strains of *R. burnetii*, and on the spread of the disease in one of the outbreaks. The story of how infection passed from a patient to a ward nurse and three members of the staff of the pathological department at the Royal Cancer Hospital is of interest because human to human spread of infection is rare in Q fever. Infection of persons performing a necropsy is perhaps rather a special instance of case to case spread which has occurred elsewhere,^{4, 11} but infection of ward staff is exceptional, though DEUTSCH and PETERSON¹² have lately recorded an incident in a Californian hospital when three nurses developed Q fever from fourteen to twenty-three days after first attending a patient with the disease. The infectiousness of a minority of cases of Q fever is not fully explained, but it is possibly related to the severity of the illness, to the amount of sputum produced, or to the cleanliness with which urine is passed. The "source case" at the Royal Cancer Hospital was producing sputum and was incontinent of urine at the end of his illness, and though DEUTSCH and PETERSON do not say whether their patient was producing sputum he was

evidently very ill. These examples of human-to-human spread should not distract attention from the fact that most patients with Q fever seem to acquire their infection from animals, either by consuming infected raw cow's milk¹³ or by inhaling dust containing *R. burnetii*.¹³ Until recently the sources of rickettsiae in the dust were somewhat obscure, for only tick excreta,¹⁴ colostrum, and milk¹⁵ had been shown to contain the organism. But the finding of large numbers of rickettsiae in the placenta of cows¹⁶ and sheep,¹⁷ and the isolation of the organism from the faeces and nasopharyngeal secretions of sheep,¹⁷ helps to remove this difficulty. DELAY et al.¹⁸ in Northern California provided direct proof of the presence of *R. burnetii* in dust when they isolated the organism from air samples collected on a dairy farm and on a sheep ranch, where human cases of Q fever had occurred.

Treatment with chloramphenicol or 'Aureomycin' has given promising results, and a prophylactic vaccine has been prepared from killed and purified rickettsial suspensions grown in the yolk sac of the chick embryo. MEIKLEJOHN and LENNETTE¹⁹ report that in their laboratory, though an unimmunised serologist contracted the disease, there have been no cases among immunised workers—an observation which is possibly significant in view of the notorious infectiousness of *R. burnetii* in the laboratory. Controlled data on the protective effect of the vaccine might be obtained by offering inoculation to workers in industries such as slaughtering, dairying, and meat packing, where the occupational risk of Q fever may be high.¹³

Flame Photometry

THE growing list of disorders associated with disturbances in the potassium and sodium contents of the body fluids already includes the oedemas, uræmias, several forms of dehydration, defects in carbohydrate metabolism and in suprarenal function, and many others. Hitherto, investigators in this field have been hampered by the tedious and difficult chemical techniques used for estimating sodium and potassium in blood and urine. But thanks to the recent developments in the physical method of flame photometry these determinations can now be done simply and rapidly, and instead of being essentially research procedures they will soon be part of the routine work of a biochemical laboratory.

The flame photometer measures the intensity of light emitted when solutions of certain metallic salts are sprayed into a flame. Twenty years ago LUNDEGÅRDH²⁰ developed an apparatus in which the spectrum produced in this way was photographed and compared with similar spectra from standard solutions. In the various types of modern instruments²¹⁻²³ the light from the flame falls on a photocell and the spraying and burning conditions are kept

constant so that the current produced gives a direct measure of the concentration of the metal in solution. Commercial models of the flame photometer are now widely used in the United States, and several British instrument makers are exploring the possibilities of building them here. Meanwhile, many home-made instruments are already working in British hospitals, and Dr SPENCER describes one of them in this issue (p 623). His experience agrees with that of others²⁴ in showing that for estimations of the alkali metals flame photometry is as reliable as the chemical methods and it is probably more reliable in the hands of all but the most expert technicians. It also saves a great deal of time, for a technician with a photometer can easily do 20 determinations of sodium or potassium in serum in two or three hours, whereas this number of chemical estimations would take a day or more. A single determination can be completed with the flame photometer within a quarter of an hour of the laboratory receiving the blood, so in an emergency the clinician can find out his patient's serum sodium or serum-potassium level in time to act on the information. Such rapid analyses are vital in the cases of potassium lack which may arise, for example, during recovery from diabetic coma or after diarrhoea and vomiting²⁵, also in patients suffering from salt depletion as a result of low-sodium diets or mercurial diuretics²⁶, and in cases of uræmia.²⁷

Turning to the working details of a photometer, the solution to be analysed (plasma, serum, or urine must first be diluted with water) is blown or sucked into a carefully controlled flame burning coal gas, acetylene, or butane. The light from the flame is passed either through colour filters, as in colorimeters, or through a spectrometer, to isolate the light of the wave length characteristic of the metal being determined. This light then falls on a photo-sensitive element (a selenium barrier-layer cell or a phototube) and the current is measured, with or without amplification, on a galvanometer. The chief difficulty lies in keeping the spraying and burning conditions constant. Some flame photometers, including Dr SPENCER's, add a known amount of some "foreign" element, such as lithium, to the solutions, so that most of the instrumental errors affect the readings from this "internal standard" as well as those from the test solutions, and are therefore cancelled out. The safest method of operation with all instruments, however, is to take readings with a standard solution of about the same strength as the test solution before or after each test. The presence of foreign elements in the solutions tested affects the light emission of sodium and potassium, and it is necessary to find out for each photometer what effects the foreign constituents of blood and urine have on the results. In some instruments sodium increases the light emission of potassium^{23, 28}. Interference of this kind can easily be corrected by preparing standard solutions of, say, potassium salts containing the interfering elements in the proportions present in normal serum.

The simplicity of flame photometry can be illustrated by comparing the number of operations necessary for determining serum potassium levels by this method and by the widely used chemical method of JACOBS and HOFFMANN.²⁹ The flame photometer requires only one reagent, and for each estimation two measurements must be made with a pipette and one reading taken of the galvanometer scale. With the chemical method four reagents are needed, and each estimation requires nine measurements of volume, two centrifugations, and one reading of a colorimeter. The stages at which mistakes can occur are roughly four times as numerous in the chemical method as with the flame photometer. The reliability of one of the home made instruments in regular use has been tested by a quality control method like those commonly adopted in industrial laboratories. The chemist in charge of the instrument prepared a series of standard saline solutions containing 250–350 mg of sodium per 100 ml to represent samples of plasma. The technician was given one of these solutions to estimate with each batch of plasma specimens, and the differences between his findings and the known concentrations were plotted on a chart. In sixteen months 150 solutions were tested in this way, with a maximum error of 6 mg of sodium per 100 ml and an average error of 2 mg.

The parts for building a home made photometer cost about £100. Few of them require skilled workmanship and all the electrical components are of standard types. The saving that it will effect in labour and time seems to justify the expenditure in all large biochemical laboratories.

Cortisone and ACTH in Tuberculosis

IN the first flush of its success 'Cortisone' was tried in America in a wide variety of diseases. Since it depresses allergic phenomena in general, and skin sensitivity to tuberculin in particular,^{30,31} it seems reasonable to use it in tuberculosis. But this must be something of an adventure, for cortisone inhibits the formation of granulation tissue^{32,33} and has been shown to do so in the tuberculous guinea-pig³⁴, it also depresses macrophage activity,³⁵ reduces the amount of lymphoid tissue in the body and the number of circulating lymphocytes,³⁵ and interferes with the formation of antibodies.³⁶ Even as an anti-allergic weapon it might prove double edged, since a "rebound" increase in tuberculin reactivity has been noted in patients when the drug is stopped.³¹ HENCH and his colleagues³⁷ briefly mention two cases of tuberculous arthritis they have treated with cortisone, and a few patients with pulmonary or laryngeal tuberculosis, mostly in the advanced stages, have been given adrenocorticotrophic hormone

(ACTH).³⁸ The results have been fairly uniform—a prompt reduction in allergic manifestations and subjective improvement while the course lasts, but doubtful amelioration or actual deterioration in the basal disease. In 13 very advanced cases, treated with ACTH plus *p*-aminosalicylic acid (PAS) and streptomycin, the results were much the same as with cortisone alone—rapid transitory clinical improvement with a general feeling of well being, but the X-ray films showed a greater tendency to cavitation.³⁹ More sinister potentialities of cortisone in tuberculosis are suggested by the experiments of HART and REES⁴⁰ at the National Institute for Medical Research in London. When the drug was given for 2–3 weeks to mice with a stable chronic pulmonary tuberculosis, there was a striking exacerbation of the disease and consequently a high mortality during treatment, at necropsy their lungs contained large coalescing necrotic lesions teeming with bacilli. In mice with more acute types of tuberculosis the course of the infection was also accelerated by the drug. Cortisone produces a similarly enhanced susceptibility to the tubercle bacillus in guinea-pigs, according to SPAIN and MOLOMUT⁴¹, and streptomycin given concurrently had little effect on their findings. Thus the hope that by fibrolysis cortisone might make the bacilli more accessible to antituberculous agents is not likely to be fulfilled, particularly since it apparently has no action on formed granulation tissue.³²

In their work with cortisone in the tuberculous mouse HART and REES have remarked that in this species, unlike the guinea-pig and man, hypersensitivity cannot be demonstrated by a positive tuberculin skin test, nor is any fibrous tissue reaction evident in tuberculous lesions, so the breakdown of resistance in the mice must be sought elsewhere—in defects of macrophage activity or lymphocytic response, or, as GREEN⁴² suggests, in depression of mitosis in the formative tissues from which these and other cells concerned in resistance are derived. HART and REES point out that their dosage of cortisone was relatively high, and that a disastrous failure in resistance such as they observed in mice will not necessarily occur in man, though it should certainly be watched for. Until we have more than the meagre amount of information obtainable from the few cases so far published, the wise course will be to regard cortisone (and ACTH) as likely to do more harm than good to the tuberculous process, and to give them to tuberculous patients only for pressing other indications. A risk whose extent cannot yet be gauged is that an unrecognised or even unrecognisable tuberculous focus may be exacerbated or activated by a course of these drugs given for approved reasons, such as rheumatism or one of the "collagen" disorders. Our best defence against this danger is to examine all such patients thoroughly for tuberculous foci, including chest radiography, before starting cortisone or ACTH treatment and at intervals during and after the course. We shall then learn how far the animal results apply to man,

without blindly risking a catastrophe. How about Addison's disease? Cortisone in small doses is said to be highly effective in this syndrome, in conjunction with deoxycortone and/or supplementary sodium chloride.⁴³ A careful watch should be kept on the progress of the tuberculosis, where that is the presumed cause of the Addison's syndrome, while cortisone is being given, even if the symptoms of adrenal cortical deficiency are relieved.

These remarks on cortisone probably hold good for the various crude extracts of adrenal cortex now on the market, some of which contain cortisone, though in very small amounts.

Annotations

R H B AND H M C

IN a short circular addressed to regional hospital boards and hospital management committees⁴⁴ the Ministry of Health explains that its resumption of the duty of approving hospital estimates, announced earlier this year, "in no way derogates from the responsibility of the boards." It is not perhaps surprising that there has been misunderstanding, and there seems to have been some difficulty in the background which the present circular does not bring clearly into the daylight. It appears to place the boards in what must seem to the outsider a somewhat unenviable intermediary position.

It is one of their primary functions to plan and supervise the provision of services, and therefore to assess the relative merits of various developments in their respective regions in accordance with broad considerations of regional planning. As a part of this duty the Minister relies on them to scrutinise closely and, if necessary, revise the proposals of the Committees for maintenance expenditure and thus prepare for him reliable estimates on the basis of which the national position can be assessed and brought under review with other claims upon the budget.

After referring to the increase in knowledge and experience of financial control which has now come about, the circular continues:

It should now be practicable by co-operation between officers of the Ministry and representatives of the Board to make a sound assessment of the claims of the various hospital units in the service. In the situation now prevailing this offers the best prospects of an equitable distribution of whatever proportion of the national resources can be made available for the purpose.

The circular seems therefore to mean that the Ministry, having tried entrusting the approval of H M C estimates to R H B s, and then having gone into reverse, has not found either plan altogether satisfactory, and now wishes itself to settle the figures, but in discussion with the regional boards.

Have we yet found a really satisfactory system for handling these matters? There is a still growing volume of opinion in the hospitals that the whole present set up, based on the submission of estimates under headings and their subsequent pruning, whether it be at regional or Ministry level, or both, is ill adapted to the needs of the service. Among the numerous difficulties is the lack of a clear distinction between the responsibility of the H M C itself for maintenance, and the responsibility of the R H B s for planning and assessing the relative merits of "developments" in their regions. In the context of this circular it certainly looks as though the board's responsibility in regard to maintenance is connected with "developments." If this could be clearly established and defined, and per contra, the responsibility of securing economy in current expenditure could be achieved by

some other means, a great improvement might be wrought. The possible alternative of letting H M C s carry the whole responsibility for the allocation of current expenditure, subject only to some central supervision of totalled figures by the Ministry, might well be tried in some selected region. If it were successful it might open the way on the one hand to round sum allocations for maintenance purposes which the H M C s could use at their own discretion and to their own great satisfaction, and, on the other, to clarifying the functions of the boards. They might then be able to deal faithfully with planning and supervision and with those aspects only of expenditure which are directly connected with "developments."

If confidence in the R H B s shows signs of ebbing a little, this is probably due as much to their inability to give adequate attention to "developments" as to any other factor. They need time and opportunity to take each item at leisure and on the spot, and for their senior officers to prepare considered reports which really do justice to the complicated situations with which they have to deal. If, as one is sometimes given to understand, the "developments" of a particular hospital management committee have to be bunched together, and taken almost en bloc, this kind of thing is not possible. The fact of the matter seems to be that in this sense the regional boards are being asked to do too much. If it is practicable to release them from responsibility for maintenance they may yet make the planning and supervision, which is their primary task, a real success.

IN THE AMERICAN HOSPITAL

THE technical and administrative sides of nursing need an ample supply of well educated women, and in the United States ways are being sought to attract such women by absolving them from constant personal attention to patients, which many find irksome. Division of labour has, indeed, already been carried a long way, and on his visit to the U S A Mr S W Barnes,¹ house governor of King's College Hospital, found as many as six categories of nursing personnel sharing the general ward duties performed by nurses and sisters in this country. Supervision and administration lay with the professional nurse, who might have had 3-5 years' training, but this included little "bedside nursing," most of which was carried on by "practical nurses" with a year's training, or by nursing aides starting with 3-6 weeks' experience. Supernumerary student professional nurses acted as assistants to the professional nurses, and finally the dietitian and housekeeper were responsible for food services and cleaning respectively. Mr Barnes does not suggest that British nursing should develop along these lines, on the contrary, he urges that more attention be paid to the comfort and convenience of nurses so that the profession shall continue to attract women who will carry on the best traditions of British nursing. He recommends the complete abolition of the two shift system, and suggests that the working hours of ward sisters be reduced. He is particularly anxious that accommodation for nurses should be greatly improved and points out that the provision of private bed-sitting rooms for junior nurses and separate sitting-rooms for senior nurses is preferable to providing numerous common rooms and lounges for general use.

Mr Barnes also makes some pertinent comments on British hospital catering, which compares very unfavourably with the corresponding American services. In the U S A, the hospital dietitian is responsible for the purchase, preparation and supply of all hospital meals and not simply (as in this country) for special diets. American hospital meals are more varied, more tasty,

⁴³ Carlisle J M. *Ibid.* II 530.

⁴⁴ Circular R H B (50) 109. H M C (50) 10.

¹ Report After Visiting Hospitals in the United States and Canada. Obtainable from the house-governors' office, King's College Hospital, Denmark Hill, London S E 5. Pp 33, 14.

and more nutritious than those served in British hospitals, and since the American cooks and kitchen staff are in no way superior to their British counterparts, Mr Barnes regards the greater influence of the dietitian as the deciding factor

DIAGNOSIS WITH TUBERCULIN

TUBERCULIN tests are not as nearly infallible as is often supposed. In a discussion not long ago at the Mayo Clinic, Stilwell¹ said that the "single strength" tuberculin test in which 0.0001 mg of PPD (purified protein derivative) is used on patients sixteen years of age or over should reveal 95% of cases in which significant tuberculosis is present. About a third of adults who react negatively to this strength are positive to the second strength dose, but "an appreciable number of the reactions may be non specific in nature".

The degree of accuracy of the test has of course been of great moment to those engaged in eradicating bovine tuberculosis. In discussing this subject Gregory² states that in a recent series in Australia about 5% of non-reacting animals were found post mortem to be tuberculous, while 10% of the reactors had no apparent lesions. Many attempts have been made to improve the specificity of the test, and in this country the comparative test is used, in which the reactions produced by the injection of avian and mammalian tuberculosis are compared.³ In the Stormont test, developed in Northern Ireland, a second injection is made, seven days later, into the site of the original injection. In 300 cattle tested and killed in Australia the total error made up of false positive plus false negative reactions was 15.3% with a single intradermal test, 12.3% with a comparative single intradermal test, and only 1.7% with the Stormont test.

The very simple tuberculin test is a most valuable epidemiological tool in investigating tuberculosis, whether in man or animals. But, remembering the complexity of the allergic state, one should not be surprised if it gives the wrong answer in some individuals.

ONE BLIND EYE

UNTREATED squint is the principal cause of monocular blindness in Scottish school children. This finding⁴ is based on the examination of nearly 210,000 school children, of whom 1713 came within the definition of monocular blindness accepted for the purpose—an incidence of 8 per 1000. There was a steep rise in incidence with advance of age, the figures being 4.4 per 1000 among entrants, 8 among intermediates, and 11.6 among those leaving school. Squint was responsible for just over half the cases, amblyopia for about one sixth, among the rest, the main factors were congenital defect and trauma. An attempt was made to obtain similar information about the adult population, but the variation between one group and another was so great as to render the figures valueless.

The incidence of monocular blindness which the inquiry revealed is higher than might have been expected, but this is partly explained by the definition of the condition laid down by the committee—corrected vision of 6/24 or less in the affected eye, 6/12 or better in the other. This is not a definition which is generally acceptable, and it seems a pity that the recognised standard of blindness (6/60 or less) was not applied. On the whole, however, the picture presented by the report is encouraging, for it shows that a high proportion of monocular blindness is easily preventable. The increase of incidence with advance of age may be due to environmental stresses, but is possibly another example of the effect of

the improved care of the last decade from which the younger children in this survey would have benefited more than the older ones.

HEREDITY AND ENVIRONMENT

LAST Monday fellows of the Hunterian Society decided by a large majority that "Heredity is more Fateful than is Environment". Opening the debate, Mr J. H. Daggart suggested that geneticists had been ill served by their friends, who in their enthusiasm had unduly decried the influence of environment. Further damage had been done by the cruel and unscientific use to which the Nazi régime had put racial theories. Nevertheless, heredity was important. Consider, for example, the ancient Greeks, who had something denied to neighbouring peoples. There was no facile recipe for producing genius, and perhaps that was just as well, for geneticists were inclined to say that genius did more harm than good. Mr Daggart supported his argument by citing an English family which had had more than its share of eminent members, and also the similarity of uniovular twins—though doubtless the proponents of the environmental theory would attribute this to intra uterine environment. Like Mr Daggart, Mr John Eastwood, K.C., was convinced of the supreme importance of heredity. Certainly, however, in his experience as a Bow Street magistrate, environment was sometimes the predominant factor because of the housing shortage marriages were being disrupted unnecessarily, and young men were sometimes going wrong because they had too much money in their pockets. As to heredity, he had been impressed by the number of cases in which the medical evidence was of a schizoid tendency and borderline mental defect and there was a strong family history of mental disorder. Mr Eastwood was also convinced that different types of crime were committed by citizens of different nationalities. Speaking for the other side, Dr J. A. Fraser Roberts declared that, as had been done with domestic animals and cattle, the human species could be changed out of all recognition, but this we did not want to do. The balance of heredity and environment was not always the same, as environmental circumstances improved, heredity became more important, whereas among backward peoples the influence of environment still far outweighed that of heredity. He acknowledged that physical traits and intelligence were primarily attributable to hereditary factors, as also were psychoses, on the other hand, general health, emotion and temperament, and neuroses were conditioned mainly by environment. (There might, added Dr Roberts, be fundamental differences between twins brought up together.) Prof J. B. S. Haldane, F.R.S., supporting the heredity thesis, enjoined caution in judging statistics, he knew, he said, of one family where 30% of the people who had married into it had become mentally ill. Nor, he suggested, could heredity be considered in isolation from environment. On a good English meadow a Jersey cow might produce up to 2000 gallons of milk a year, while the Galloway on the Scottish moor was yielding only 200. Put the Galloway into the meadow and its yield might double, but put the Jersey on to the moor and it would lie down and die. He, too, believed that with a regulated and constant environment heredity was the more important. But man's environment was neither regulated nor constant—the expectation of life for the child born in India or China was half that for the child born in England. Furthermore, "you will know more about me if I say I was born in Southern England than if I say my father was a professor and not a bricklayer".

Dr Gösta Forssell, formerly professor of radiology at Caroline Institute and director of the X-ray department of Caroline Hospital, died in Stockholm on Nov. 14, at the age of 74.

RESEARCH ON BURNS

An American Symposium

FROM A CORRESPONDENT

At the opening of this symposium, held in Washington on Nov 2-4 by the National Research Council, Dr M C WINTERITZ, chairman of the council's division of medical sciences, remarked that work in this field went beyond surgery, needing a combined approach by physiologists, chemists, and physicists as well as clinicians

SCOPE OF THE BURN PROBLEM

Dr EVERETT EVANS, chairman of the council's sub-committee on burns, said that at Hiroshima blast caused 45% of the casualties, thermal effects 40%, and radiation effects 15%. With modern phosphorus and petroleum types of bomb 59% of deaths are due to burns, while 25% are due to blast. He drew attention to the serious nature of combined injuries, especially when blast or thermal injuries are combined with exposure to ionising radiations, even in low dosages

RADIATION COMPONENT OF ATOMIC BOMB EXPLOSIONS

Dr WILLIAM T HAM, jun, said that in above ground A bomb explosions, 2000 ft is the most destructive level. The thermal hazard is not serious in ground and below water level explosions. In plutonium fission some 60 types of radiation products are released. Very little radiation escapes at first, because of local absorption, only 3% of total radiation arrives during the first $\frac{1}{100}$ second. The "mushroom" goes up at 300 ft per second. It takes 60-100 seconds for the total γ radiation to reach 4200 ft from the bomb. γ rays passing through matter are continuously degraded in wave length, 16 in of water reduces these rays to $\frac{1}{10}$ of value, and 20 ft of concrete at 400 ft from source will reduce 400 r to 20 r. Fission neutrons are mostly captured in the immediate vicinity of the explosion, only a small percentage is thought to become a radiation hazard. The neutrons released are either "prompt" or "slow". There is no information yet regarding lethal dose of "prompt" neutrons. Absorption of neutrons of both types is probably fatal at 3000 ft from the bomb. Dr Ham noted the high incidence of cataract amongst cyclotron workers, 200 rep of "prompt" neutrons produces a cataract. Therefore cataracts occur at 1900 ft from the bomb, but in Japan cataract has occurred at 3600 ft. At 4200 ft the M.L.D. of γ radiation is 900-1000 r, and of neutrons it is 3600 rep.

Commander E P CRONKITE stated that certain biological phenomena observed after ionising radiation are inconsistent with the known physics. Thus the exposure of 7 MeV necessary to produce epilation greatly exceeds the diffuse radiation exposure known to cause death. Shielding—for example, of the spleen—can increase tolerance to exposure. Considerable protection is afforded by getting behind the concrete in the first 30 seconds after the explosion.

PHYSIOLOGICAL PROBLEMS CONCERNED WITH FLAME THROWERS

Dr JAMES M WALKER said that in the late war deaths after exposure to flame throwers occurred for the most part within minutes. Patients with severe total body burns may live some hours, but death may take place very quickly with slight external burns, these deaths are thought to be due primarily to heat, but decrease in oxygen tension and increase in carbon monoxide are also important.

Experimental studies of petrol burns in pigs (some times with the body but not the head exposed to heat)

have shown that death can take place through three mechanisms (1) hyperthermia, (2) hyperthermia plus cardiac failure, and (3) cardiac arrest due to the release of concentrated potassium ions from haemolysed red blood cells.

In flame throwers the temperature may go up to 1000°C. There is a difference between the effects of hot dry air and of hot air plus steam, since steam produces pulmonary oedema as well as burns of the upper respiratory tract. There are also differences between the effects of static flame and of high velocity flame. The deaths in Japanese bunkers attacked by flame throwers were, therefore, studied with special attention to carbon monoxide poisoning and low oxygen tensions. Experiments with goats in bunkers and in slit trenches showed that with 34% dead on open ground only 2% were dead in trenches. These dead goats showed only slight external burns, but carbon monoxide poisoning and low oxygen were not sufficient to account for the deaths. A third of the animals showed evidence of laryngeal obstruction, the deaths were therefore ascribed primarily to hyperthermia. In bunkers, after exposure to 800°C, some animals had potassium effects on the heart.

When flame throwers are used on bunkers with temperatures up to 400°C, oxygen lack and toxic absorption of products such as acetaldehyde are important, as is carbon monoxide increase. If water is on the floor, steam can produce laryngeal and pulmonary oedema. Lethality is increased by combination of all factors—i.e., heat, low oxygen, high carbon monoxide. In goats a 70-80% surface burn at 700°C will produce a "potassium death".

LABORATORY PRODUCTION OF HIGH AND LOW TEMPERATURE BURNS

Dr HERMAN E PEARSE pointed out that evaluation of experimental high temperature burns is by description of gross pathology only. We have not yet a quantitative yardstick to assess biological effect. An attempt has been made to reproduce the thermal component of an A bomb—that is, a high quick release of energy attenuated by passage through atmosphere. Dr Pearse referred to the effect of fabrics, both in protection and as a danger in causing secondary burns on ignition. Experimental sources of heat are (1) electrical discharges, (2) ignition of thermite or magnesium, and (3) constant source of heat from a carbon arc, or the sun (by mirrors). No method is ideal. There is need of further research for precise knowledge of depth of tissue penetration, and of energy emitted.

Dr W J H BUTTERFIELD described work in Britain since 1947 on the thermal effects of A bombs, and means of protection and treatment. This research had been directly concerned with spectral range, clinical course, and healing times. The experimental material had been the bodies of the workers themselves and of volunteers among co-workers. The threshold of response was related to area exposed, the larger the area, the lower the threshold. The red part of the spectrum was believed to be more important than ultraviolet light as a source of A bomb burns. Infra red rays, produced by a coal gas machine had been applied to areas of skin of 5, 3, and 1 sq cm, with the source of heat at a distance of 11 cm for 11 seconds. This exposure was thought to equal the thermal component of an A bomb at 4500 yards from the hypocentre. The clinical course of the burn was plotted. There was erythema, dull pain, oedema, and blisters which went on forming for up to 24 hours. Desquamation occurred at 7-10 days, healing was complete at 14 days. There was some late pigmentation. On exposure of 1.3 seconds to 4 calories burns with full thickness skin loss were caused. Such full thickness skin burns might be expected at 3100 yards from an A bomb, at 4800 yards

only erythema would be expected. The wider the area exposed, the lower the threshold. A bomb heat rays were rectilinear, most exposures would be glancing, and therefore less severe for the given distance. Dr Butterfield also described the results of white light burns, whose clinical course differed. In the absence of infection, healing and distance from the A bomb bore a linear relation to each other. If there were 1000 people per sq mile in a city exposed to an A-bomb, 1600 could be expected to be exposed within a radius of 3000 yards, this would result in incapacity amounting to 150,000 man days, provided the burns healed without infection.

Dr Butterfield emphasised that his experiments were not concerned with the constitutional effects of the burns, but solely with the local lesion, and in particular with obtaining precise information about extent and clinical course of lesions produced by measured exposures in known lengths of time which were related as closely as possible to the presumed exposures to the thermal component of A bombs.

Dr JAMES W BROOKS described the results of standard burns produced by relatively low temperatures at long durations. Area and depth were constant, healing was spontaneous and was not associated with serious infection. The lesions were produced on the trunk not near orifices, dogs were used as their response to burns is similar to that in man. Deep second degree burns were produced. By means of a formula the exposure to produce a 20% body surface burn could be measured accurately. Healing was by marginal ingrowth after separation of sloughs, which was accelerated by the dog licking the lesions, it was complete, on average, by the 42nd day. The effects included falls in haemoglobin percentage and in protein in the first hour, and 25% decrease in cell mass due to enlargement of spleen under sodium pentobarbitone. After 20 days there was a gradual rise in haemoglobin, red blood cells, and blood protein during the healing phase.

The experiments were then repeated, the dogs now being given, in addition, 100 r total body radiation from 1-MeV source at 30 r per minute. In a third experiment only the radiation of 100 r was given. Studies of haemoglobin, red and white blood cells, and plasma protein showed little difference between the different series in the first 24 hours. But the anaemia was more rapid and more severe in the group both burnt and irradiated, the white cells remained steady for 6 days and then dropped rapidly by the 12th day, in this group blood cultures became positive, mostly with streptococci, by the 12th day. Necropsy showed little change in intestines, the bone marrow showed a great drop in all cellular elements (in the fatal burns with out irradiation the bone marrow showed a myeloid preponderance).

Other experiments with different dosages were described. Exposure to 25 r plus a 20% thermal burn caused leucopenia starting on the 10th day, as opposed to the 6th day when the exposure was 100 r. The mortality for each group was as follows: 20% burn, 13%; 20% burn plus 100 r, 75%; 20% burn plus 25 r, 33%; 100 r alone, 0%.

FLUID AND ELECTROLYTE REQUIREMENTS

Dr DONALD D VAN SLYKE emphasised that shock is due to loss of blood, plasma, and electrolytes, and it is best combated by replacement of these. The chief problem is to find a replacement fluid for plasma and blood, for which the demand would be too great.

Electrolytes and Water—Dr OLIVER COPE pictured the burn wound as a parasite on the surface of the body. Of all local measures, only two are certain to limit needs of fluid by reducing local loss: these are pressure and cold. Recently there has been evidence that a CTN

might also do this. The object is to replace in the rest of the body the fluid lost in the wound. Thermal wounds swell rapidly owing to capillary permeability and arteriolar dilatation, with increase in rate of blood flow through the affected part. Volume loss is proportionate to area and mass of burn, it is limited by the rising intercellular pressure in the burnt areas. The protein content of the burn bleb is at first 3–4.5 g per 100 ml, and with healing falls to 2 g per 100 ml at 7 days. There is a great increase in lymph drainage and in the protein content of lymph from the part. Local oedema reaches a peak at 36–42 hours. At 48 hours the capillary membranes become less permeable, the lymph drainage rate is high, therefore oedema starts to subside rapidly at this time, circulation and kidneys must rid the body of this excess fluid. Unburnt areas of the body are dehydrated, so that all lymph flow from them ceases. If the burn is not fatal, fluid redistribution takes place.

Plasma provides water and electrolytes, but too much protein, it is therefore a good, but not an ideal, infusion agent for burns. The object should be to give colloids and electrolytes in the volume necessary to replace that lost in the burn, locally pressure dressings are applied to restrict local volume loss, for unsupported burnt areas develop "puddles." Pressure is a useful adjunct. Cold can also limit local loss by reducing capillary flow.

This plan of therapy based on expected volume of space enlargement is still experimental. Fluid should have both colloids and electrolytes plus water for renal function. "The percentage body surface affected formula is best for planned therapy," provided it is adjusted up and down in accordance with the needs of the particular case. The need for fluid is greatest in the first 1–8 hours after burns. The rate of renal output is the best guide to the rate of fluid administration. Dr Cope especially stressed that fluids must be sharply curtailed 36–48 hours after the burn.

Dr O J PURNELL declared that lives may be lost by pulmonary oedema or by anuria. In children and the very old it is particularly difficult to assess fluid requirements, if too much is given, fatal pulmonary oedema ensues on the 3rd–6th day. 15 ml of blood plus 15 g electrolyte for each 1% surface area burnt is the formula that has been used, but this may be too much. Dr Purnell now gives 2.6 ml per kg body weight per 1% of surface area burnt on the first day, and 1.6 ml on the second day. He believes that the customary formula of 50–100 ml per 1% body surface burnt may be too little and lead to anuria. He therefore suggests 1 ml plasma per 1% per kg, plus normal electrolyte solution of 1 ml per 1% per kg, plus water up to 2000 ml in 5% glucose. Not more than 3000 ml of electrolyte or plasma is given per day, there should be an excretion of 50 ml of urine per hour. He never gives more than 10,000 ml of all fluids in the first day. Sometimes death takes place even with a good urinary output.

Giving colloids, fluid, salt of 1 ml per each 1% surface area burnt per kg body weight, plus 2000 ml of water by mouth, followed by half this amount on the second day, Dr Purnell has had no cases of pulmonary oedema or of anuria. This means an upper limit of 3000 ml each of colloid fluid and of salt fluid. If more is given, pulmonary oedema is caused.

Albumin, Plasma, and Whole Blood—Prof DICKINSON W RICHARDS, jun, described a study of the circulation of 200 cases in the acute stages of burn and traumatic shock. Blood volume, right auricular pressure, cardiac output, femoral artery pressure, and peripheral resistance were measured in each case. With burns there was a fall in the cardiac output, less fall in the right auricular pressure, and a rise in the peripheral resistance to above normal. This picture did not explain the deterioration in these patients. The disorganisation of circulatory dynamics was not proper

tionate to the local conditions. These measurements were made following the administration of blood and saline. Administration of blood increased the cardiac output, the oxygen pressure, and the pressure in the right auricle. Concentrated albumin fluid had the same effect, but to a smaller extent. Saline had an even less marked and a more transient effect.

Dr CARL A. MOYER had tried to produce the thermal injury experimentally so that it could be studied like a pharmacological problem—that is, what thermal injury would have an M.L.D. of 100% in 8 hours? He found that all dogs scalded to 60% surface with water at 85°C for 10 seconds died in 5–6 hours. He did a series of controls and then a further series after “loading” the dogs about to be burnt with various types of fluid. Dogs loaded with saline, bicarbonate, and blood mixture showed a great rise in the proportion surviving for 60 hours. Animals given blood and allowed to drink salt water survived 80 hours. Dr Moyer underlined the importance of loss of red blood cells into the dilated capillaries of the burnt area, and of the slow blood flow there. He regarded the urinary output as an important guide to rate and amount of fluid administration, but added that patients do not respond uniformly.

Dr Moyer gave the results in a series of burns treated in Dallas, Texas, all with involvement of 30% or more of the body surface. In 1944–48 cases were treated chiefly by plasma, 3–12 litres in 12–36 hours, plus water by mouth. The 1947–49 group were treated by blood plus salt water by mouth. In both groups age had a very adverse effect, no patient over 60 survived with more than 30% body surface burnt. Four patients had been seen comatose with very tight trunk dressings, they had recovered consciousness when these were released. Dr Moyer referred to the difficulty in taking fluids by mouth with burns of more than 30% of the body surface, the stomach emptied very slowly when shock was present.

Dr ARNOLD M. SALZBERG had estimated plasma-volume by the T1824 dye technique. The red cell volumes were estimated by the plasma volume/venous haematocrit formula. The red cell volume was also estimated by means of radioactive phosphorus (P^{32}). In dogs standard burns were inflicted by exposure to 60°C for 1 minute to 20% body surface. The red cell count by the P^{32} technique differed from that by the plasma volume/venous haematocrit technique formula. The reasons for the discrepancy lay in the error in the venous haematocrit reading which was influenced by variations in individual red-cell volume. It was therefore thought that the dye technique did not yield accurate data for replacement therapy. After the primary phase the replacement therapy demanded the giving of blood, if the P^{32} readings were correct.

Large amounts of whole blood in the first 24 hours helped healing and prevented late anaemia, the initial loss of red blood cells accounted for much of the late anaemia.

Globin—Dr MAX M. STRUMIA held that, when oral feeding is impossible, globin is a valuable substitute for protein feeding, it is indeed a good replacement material when plasma proteins are lost from any cause. Globin is readily metabolised, a 4% solution is isotonic with 7% plasma protein. Globin is a salvage material obtained from discarded red blood cells, 40 g is obtained from 500 ml of blood.

Dr ROBERT B. PENNELL said that with Dr Strumia's method of manufacture from unwashed red cell residues (of any blood group), the globin product is stable for years when dry or in solution, it is free from antigen, it can be used in strengths of up to 16% without toxic reaction. It contains no potassium but some iron and some calcium. A study of the use of modified globin in burns has shown that it is a valuable substitute for plasma in the treatment of shock. At the moment it

affords the only possible means of salvaging outdated red cells.

Dextran—Dr GUNNAR THORSEN (Stockholm) described six years' clinical and experimental experience with dextran. Urinary excretion is proportionate to the molecular weight of the dextran used and the total volume given. When $1\frac{1}{2}$ –1 litre is given, nearly all is excreted in 2–4 days, but some remains in organs such as the liver. 1 g of dextran binds 23 ml of water. Dextran does not cause anaemia, the bone marrow of patients receiving it shows no abnormal cells. The critical molecular weight is slightly above that which is filterable through the kidney, the molecules should be large enough to stay in the blood without causing sludging. The only complication of importance has been some collapse and substernal pain in 0.02% of cases. In burns dextran is as good as plasma, in the early phase 1 litre of 1% dextran is given alternately with 400 ml. of blood. There have been no cases of “wet” lungs. Dr Thorsen especially emphasised the value of dextran as emergency treatment in the field or in outlying hospitals.

Dr J. P. BULL (Birmingham) gave an account of experience with dextran in the Medical Research Council's burns unit. The large molecule polysaccharide used commercially has to be broken down by hydrolysis. Dextran molecules are made up of glucose with 1–6 linkages, these break down slowly and are in the circulation longer than one would expect. Dextran is given in the first 24 hours after the burn, blood is given later. The amount given is determined by haematocrit readings. Dextran can be swapped bottle for bottle with plasma. In an adult, about 1 litre of plasma is given for every 10% of body area burnt, plus sodium lactate by mouth. If a lot of dextran is given, plasma proteins fall (in one patient, who died, to 3 g per 100 ml.) In neither patients nor animals has there been evidence of toxicity or of pyrogenic or antigenic activity. In the body dextran has a half-life of 40 hours. About 30% can be recovered from the urine. The fate of the rest is uncertain but after some months the organs contain no substantial amounts, it disappears last from the lymph glands. Dr Bull remarked on the difficulty that dextran may cause in cross matching of blood because of its tendency to provoke rouleaux formation, patients who may need blood have samples taken for cross matching before any dextran is given.

Gelatin—Dr J. L. O'CLEY discussed the preparation of degraded gelatins suitable for use as plasma substitutes. Ossein gelatin is degraded into a series of shorter chains, the shorter the chain the lower the molecular weight. D gelatin is that most often used clinically, it is characterised by viscosity and by its osmotic effect. Degrading may be done by different methods.

Prof I. S. RAYDIN described clinical experience with gelatin over the last nine years in Burma, India, and America. He has used the P20 gelatin in 4% solution. He declared that if blood is available there is no need to worry about substitutes for it. In burns the need is for a substitute product exerting a colloidal osmotic pressure over hours rather than days, the gelatin solutions are suitable for this. Some degraded gelatins cause serious renal damage, but P20 does not. Other drawbacks include lack of homogeneity, and the variety of molecular weights. An extensive trial of P20 gelatin has shown it to be very satisfactory when used in a 6% solution, plus other fluids. 50% of the gelatin is lost in the urine in 4–5 days. The use of low-molecular sizes reduces to a minimum the risk of intra-vascular clot. Professor Raydin believes that, when given in hospitals, it is as safe as blood.

Dr EVERETT EVANS has found P20 better clinically than the more degraded gelatins. He has administered

to a child 200-400 ml of 4% solution four times in 24 hours. In his opinion, P20 gelatin is clinically an effective plasma substitute for cases of burns.

RENAL AND PULMONARY DISTURBANCES ACCOMPANYING SEVERE BURNS

Renal Disturbance—Dr CHARLES H. BURNETT said that serious renal insufficiency is rare after prompt full treatment of civil burns, but after military and A bomb burns it is common. Mallory has demonstrated a lower nephron nephrosis after severe trauma, crush injuries, transfusions, and excess sulphonamides. There is a shock-like state with excretion of myohæmoglobin and hæmoglobin. On days 1-6 casts are present without glomerular change, at 7-10 days tubular casts appear.

The management is that of acute renal insufficiency of lower nephron type. This management comprises (1) re-establishment of homeostasis, (2) maintenance of homeostasis during period of oliguria, and (3) maintenance of homeostasis during period of diuresis. In burns a special problem is the excess of fluid which has to be got rid of between the 2nd and the 4th days. The serum sodium is a good guide to therapy, it may be urgent in the period of change from oliguria to diuresis. Deficiency of serum sodium may lead to sudden collapse. Acidosis in this phase of oliguria should be remedied by treating the cause, but it is unwise to be too energetic about the correction of the serum carbon dioxide. Severe alkalosis may be caused, and be more dangerous and difficult to correct than acidosis. During the oliguria only 750-1000 ml of fluid is given. The nutrition is maintained by 10-25% glucose. At this period an excess of serum potassium may be present, owing to breakdown of red blood cells. If the circulation is stabilised protein should not be given during the oliguria, this would increase the serum potassium. Dialysis is not generally necessary, but may be valuable in burns with lower nephron failure. Once diuresis sets in, extensive depletion of sodium, potassium, calcium, and chloride may occur in the absence of replacement. Renal insufficiency is preventable, but with mass casualties acute kidney failure is to be expected. The treatment is that of the lower nephron syndrome complicated by the nature of the fluid loss in a burn.

Experimental Pulmonary Injury—Dr ALAN R. MORITZ said that respiratory tract damage is common in burns and is not proportionate to the extent of the skin lesion. Not only heat but also combustion products of any fire can cause pulmonary injury. Hot air was delivered into the upper respiratory passages of dogs at temperatures of 350-500°C, from different heat sources, with and without protection of the larynx. The dogs were allowed to breathe 120 times. Early deaths were due to laryngeal oedema, with little changes in the lower trachea or lungs. Air even at 500°C is not hot enough to maintain its temperature into the lungs. In another series a steam jet was introduced into the lungs. When hot air was passed into the larynx a fall in temperature of 350°C to 180°C was observed without pulmonary injury. With a flame at 1000°C at the larynx there was severe damage in the upper trachea, some early pulmonary damage, and late bronchopneumonia. When steam at 100°C was passed into the larynx 50% of the dogs had moderately severe thermal injuries of the alveoli around the medium to large bronchi. Why is it that air hot enough to damage skin does not damage the lungs? It is because the heat capacity of air is $\frac{1}{1000}$ that of water. Only when the temperature of air is high enough to burn skin instantly is the lung tissue affected, and then the lung damage is not incompatible with life. Only when the larynx is protected does fatal thermal pneumonitis develop. If the larynx is not protected death occurs from early laryngeal obstruction. The most vulnerable part of the lungs is the central

alveoli, which can show hæmorrhagic oedema when the neighbouring bronchi are unaffected.

Respiratory tract Injury in Man—Dr MAXWELL FINLAND recounted experience at the Boston City Hospital of the Boston Coconut Grove disaster nine years ago. In this disaster people were confined in a rapid conflagration, there was a big proportion of early deaths. At necropsy of the victims the mucosa of the upper respiratory passages were red, oedematous, and hæmorrhagic, these signs diminished towards the bronchi. There was no froth, but a dripping pulmonary oedema limited to the alveoli, possibly due to an irritant and not to the flames.

Cases were classified, according to severity of respiratory symptoms, in five groups, ranging from those with a slight cough to those with consolidation plus respiratory obstruction. There was close correlation between clinical signs and X-ray evidence of atelectasis and emphysema. There was also correlation between the extent of surface burns and the pulmonary findings. The deaths were in two groups: (1) cases with burns of over 30% body surface, and (2) cases with signs of pulmonary consolidation or of consolidation plus obstruction. The obstruction sometimes came on very suddenly, these cases needed most careful watching. Administration of fluid was difficult because of the danger of pulmonary oedema. Tracheotomy was done in 18 cases, only 3 survived. Respiratory obstruction was a major factor in the 39 fatal cases.

The nature of the noxious gases was not ascertainable from the patients' history, but in some cases carbon monoxide poisoning was a factor. A late follow-up has shown no important or persistent damage to lungs in survivors. The pulmonary damage in the fatal cases was due to multiple causes, primary and secondary. The best management of the chest condition would appear to be comparable to that of children with severe laryngo-tracheo-bronchitis. In the cases seen at Massachusetts General Hospital the pulmonary oedema occurred in waves at 5-24 hours.

STRESS, INJURY, AND ENDOCRINE RESPONSE

Prof GEORGE W. THORN divided the humoral factors in severely burnt patients into three systems.

System A is in the burnt area. It concerns the liberation of substances and their action on the kidney and the liver. We should note that the rate of absorption of toxins is increased by fluid administration, and we should ask if this is always a good thing. System A also stimulates system B.

System B is the pituitary action brought into play in response to the toxin from the burnt area, and in its turn stimulating the adrenal cortex, leading to an outpouring of adrenal steroids. Is this always entirely a good thing for the burnt patient? And is the output of steroids adequate or optimal? In a state of stress adrenal replacement dosage, if desirable, would have to be very high. There is excess 17-ketosteroid and 11-ketosteroid excretion, but what this really indicates is unknown. System B is linked with system C.

System C is the renal-hepatic system. This maintains the blood pressure by excretion of pressor substances from the kidney and/or depressors from the liver. A fall in blood pressure may be due to excess depressors or diminished pressors.

In burns there is intense inflammation. ACTH will minimise this, hyaluronidase may be blocked by 'Cortisone' or by ACTH. Synthesis of histamine is also reduced. Most of the usual body reaction to injury is therefore blocked by giving ACTH.

ACTH and cortisone can reduce the fever, but it is uncertain whether this is entirely beneficial. These hormones also modify the liver reactions, helping to mobilise fat and save proteins, their effect on blood formation is to cause leucocytosis, they may also prevent

the formation of a pyrogenic membrane. This probably means that they should only be used in association with antibiotics. A.C.T.H. influences the production of hyper-tensinogen by the kidney, in 7-10 days it causes an increase in peripheral resistance by its effect on capillaries and arterioles.

Patients who have their blood dialysed for 6 hours show a rise in blood pressure even when not previously responsive to pressor substances, depressor substances have therefore been removed by the dialysis. Dialysis may be used instead of blood in cases of pulmonary congestion. After 6 hours' dialysis the patient may again respond to pressor substances. Dialysis is a method with great potentialities. In shock it may possibly be necessary, not merely to *give*, but also to *withdraw*, substances—e.g., the depressors secreted by the liver.

Relation to Burns—Dr J. S. L. BROWNE (Montreal) said that the adaptation syndrome is the common response to a variety of stimuli. The response varies with time, it is also modified by previous stimuli. The urinary hormone content is only a rough indication of the hormonal activity and internal balance. What is an adequate output of hormones? It varies widely with the state of the organism. Both urinary nitrogen and corticoids rise after injury or burns. Testosterone checks nitrogen loss, but it may simply be transferring protein from the site of injury to other parts. Continuous A.C.T.H. will cause a rat to lose weight and die in 9 days with all organs showing a lowered nitrogen content, and patients in trauma are already in negative nitrogen balance. It should be noted, too, that different tissues have different capacities to seize nitrogen.

When a patient with burns receives 1000 mg. of ascorbic acid, none appears in the urine for some days and the blood level remains low. The effect of A.C.T.H. is to cause vitamin C to appear in the urine when administered in heavy doses. This phenomenon has great potential value. Homografts persist for at least 140 days when A.C.T.H. is administered.

Metabolic Response to Thermal Injury—Prof. FRANCIS D. MOORE suggested that a thermal burn is a disease with a natural history and a characteristic succession of events. With plasma therapy the patient is put in positive nitrogen balance, then high nitrogen excretion follows with a negative nitrogen balance, before return to a positive nitrogen balance with healing. There is a short period of potassium loss, and often a period of notably positive sodium balance. This may be due to corticoid production and secretion. Other factors are immobilisation and starvation, starvation is the more important. Professor Moore's estimate is that $\frac{1}{3}$ of the response is due to immobilisation $\frac{2}{3}$ to starvation, and $\frac{2}{3}$ to endocrine reaction. In a burn the negative nitrogen balance can be checked by late loading with protein, and the negative potassium balance by early loading. The early endocrine picture is that of extreme adrenal stimulation going on to exhaustion, this points to the need of A.C.T.H. In some cases 300 mg. cortisone is given for the first 3 days then 120 mg. A.C.T.H. daily. 2 mg. of cortisone does not interfere with the healing of a herniotomy wound. Relatively enormous doses of A.C.T.H. are needed to interfere with the healing of experimental wounds. The caloric deficit is treated by fine fat emulsions (of coconut oil) given intravenously.

TREATMENT OF THE BURNED AREA

Closed dressing Principle—Dr HARVEY S. ALLEN reported on 955 cases admitted to hospital since 1938, with a mortality of 1.78%. The routine is to cleanse the burn with saline and to treat the shock by fluids. Locally a pressure dressing is applied for 6-10 days. Sloughs are then excised and grafts applied forthwith, or 4 days

later if oozing is heavy. In 45% of children the wounds were closed in two weeks, and in 86% in three weeks. Pressure dressings are regarded as important, they must be of large resilient material with a close mesh underlayer, and must act as splints. Antibiotics are used only for established infections. Of this series, 30% showed clinical shock on admission, 25% needed grafts, and 17% needed excision of dead tissue. In 44% grafts were applied within 2 weeks, and in 85% within 3 weeks. Dr Allen emphasised the importance of this early grafting. "The impetus to heal is quickly lost. I do not believe that we can apply drugs to a wound and expect healing."

Dr BULL said that the pressure exerted by properly applied pressure dressings ranged from 30 to 50 mm. Hg.

Mr PATRICK CLARKSON (London) drew attention to the dangers of pressure dressings applied to the neck, especially in burnt children. He has had some experience of the exposure method, and has found its practicability in the treatment of superficial burns in general hospitals a great asset. He complimented Dr Allen on his success in reducing mortality in such a large group, including many of the most severe types, to 1.7%. This, he is sure, is the result, not only of Dr Allen's exceptional skill in the operative handling of these difficult cases, but also of his energetic plan of management, by which he excises the sloughs and provides a free graft cover for over 80% of his cases within the first 10-20 days. This is a most exacting programme, but its successful accomplishment obviates many problems.

Exposure Method—Lieut. Colonel EDWIN J. PULASKI referred to the reintroduction of the exposure method of local treatment by Wallace in 1948. The object of this method is to obtain and maintain a dry surface after cleansing with a detergent. The affected part is elevated and immobilised. The area of full-thickness skin loss is excised after 20 days and grafted. Results obtained by the U.S. Army in Texas confirm for adults in a semi-tropical climate Wallace's findings in Edinburgh. The advantages of exposing the burn area are as follows: there are no pressure dressings, which are difficult, dangerous and time consuming to apply, the marginal skin is rarely macerated or lost by secondary infection; there is no odour; there is a short period of pyrexia, nursing care is reduced, healing times are short, and grafting is less often needed. Exposure is a hospital procedure, and not for outpatients, it is probably unsuitable for circumferential burns because parts of these are in contact with the sheets. The method is particularly suitable for burns of the face and neck and of the perineum, and for unilateral burns.

Mr A. B. WALLACE (Edinburgh) reviewed experience of over 300 cases treated by this method during the past three years. His treatment of burns is by "controlled fluid therapy and local care". Clinical signs—thirst, pallor, restlessness—precede blood-changes and are indications for intravenous fluid. Tables of normal haemoglobin percentages, hematocrit readings, and urinary output for different ages are kept and are constantly referred to when assessing fluid needs. Fluid replacement is based on age and the estimated percentage body surface burnt in accordance with a chart which has been constructed in his department. (The water, protein, and electrolytes in this chart for fluid replacement are very similar to the figures arrived at independently and from different evidence by Professor Evans in the U.S.A.)

Cultures of the exposed burnt area have never shown growth of haemolytic streptococci, proteus, or *Pseudomonas pyocyanea*, though these organisms were often demonstrable in the air of the ward. Mr Wallace compared 100 cases treated in his children's ward by exposure of the burns with 100 cases treated earlier by pressure dressings. Of the exposed cases 9 needed

grafting, of those with pressure dressings 27 needed grafting. None of the exposed patients had fever for 1-6 weeks, 34 of the patients treated with dressings had such a fever, and 5 of this group had streptococcal rashes, which were entirely absent from the exposed group.

Mr Wallace said that the exposure method is used by him as a means to an end—this end is to obtain a dry skin with maximal preservation of the skin's natural property of resistance to infection. He believes that a dry skin could probably also be obtained by an absorptive dressing. In his view the term "pressure dressing" is wrong, it should be replaced by the term "absorptive dressing." The two methods—exposure and absorptive dressings—are complementary rather than mutually exclusive. There are indications for the use of each.

INFECTION IN SEVERE BURNS

Mode of Infection and its Control—Dr LEONARD COLEBROOK, F.R.S., reviewed his very extensive experience while in charge of the M.R.C. burns units in Glasgow and Birmingham. The Glasgow burns were treated largely without antibiotics.

"The bacterial factor is the biggest in severely burnt patients." 90% of severe burns are complicated by infection, which postpones grafting and healing and causes unnecessary disability and unnecessary deaths. The tradition that in severe burns infection is inevitable is wrong; infection can be avoided. Today many cases of 60-70% body surface burns recover. Dr Colebrook reserved his judgment of the exposure method of treatment.

In Birmingham the policy was to regard all burns as liable to infection and needing treatment under a microbe proof barrier. This meant doing all dressings in a room with sterile air, and the use of topical penicillin. Dr Colebrook showed slides demonstrating relatively simple air conditioning apparatus, whereby an effective rate of air replacement from above down at 20-30 replacements per hour ensures a virtually sterile environment within the dressing room. The value of this sterile air has been difficult to assess, because a strict dressing technique and topical penicillin were used concomitantly. But the overall effect of these three factors was most striking. Thus, in Glasgow, without the dressing room, the infection rate with haemolytic streptococci was 30%, at Birmingham it was less than 5%. At Birmingham, too, many burns were kept completely sterile for 2-3 weeks. The average stay in hospital has been reduced by 50%. Clinically pain has been largely eliminated, and throughout treatment the morale of patients is good.

Dr Colebrook made a special plea for the establishment of burns centres in all large cities. About 100 beds per 1,000,000 population are necessary in England, in the U.S.A. burns are about twice as common, and 200 beds per 1,000,000 are probably necessary. He also drew attention to the possible conversion, for war purposes, of ambulances into mobile dressing rooms with sterile air produced by air conditioning at a high rate of air replacement. Another urgent need is the determination of a simple dressing (to be left on for a week) for hand and face flash burns.

Dr Colebrook declared that, in the event of mass casualties, streptococcal infection might again be seen in its old, dangerous, and epidemic form. Our present relative freedom is due to penicillin, to small numbers, and to conditions of treatment which could not be expected to prevail with mass casualties.

Antibiotic Therapy—Dr WILLIAM A. ALTEMEIER said that the majority of U.S. doctors prefer systemic to topical penicillin. Each antibiotic has a limited antibacterial spectrum. Penicillin has the widest range,

chloramphenicol the next widest, and then 'Aureomycin' and 'Terramycin'. Terramycin is effective against the highest percentage of cocci and gram negative bacilli, this is to be expected since it has been used only for a short time. Antibiotics are only a temporary measure in the control of infection in deep burns, these need surgical removal of the sloughs and a graft cover.

NUTRITIONAL CARE

Burn Anæmia—Prof G. WATSON JAMES outlined the biochemistry of the formation of hæmoglobin from a globin and from an iron containing hæm fragment. On breakdown the iron is retained by the body, the pigment excreted. The progenitor of the red cell is the site of the synthesis of hæm and globin into hæmoglobin. The resources for this are brought to the cell by the plasma. If the plasma protein (including glycine) is low there is normoblastic arrest. Any disturbance of porphyrin metabolism probably indicates severe disorder of red cell metabolism. He drew attention to the large amount of red cell mass that disappears after the dressing of extensive burns. In burn anæmia the hæmoglobin tends to settle at about 8-10 g per 100 ml. He concluded that the anæmia requires, for its radical treatment, the removal of dead tissue and healing by grafts.

Nutritional Care—Dr STANLEY M. LEVENSON spoke of the adverse effect on nutrition of combined radiation and thermal damage. Routes of feeding are by mouth, stomach, jejunum, or vein. Optimal amounts have not yet been determined, but high intake in the first week is always beneficial. The most useful diets are liquid, given as regular small feeds, with a calorie content of 3500-5000 and protein totalling 100-250 g. (When milk is the major protein source, there may be danger of calculi.) A thin plastic nasal tube may be left for up to 5 months, with weekly removal for cleaning, this permits administration of protein in the form of unpalatable liver feeds. 20% of calories should be from fat.

Dr FREDERICK J. STARE declared "I do not know what an adequate caloric intake for a severe burn is." A fine emulsion of coconut oil, in addition to providing calories, confers efficiency of utilisation on other elements in the diet. The average particle is $1\frac{1}{2}\mu$, none is larger than 3μ . With oral administration all the fat is absorbed, none is recovered in the faeces. The emulsion is palatable and can be used as a solvent for vitamin K. (When so combined and given intravenously, it can correct the effects of dicoumarol in 12-24 hours.) The emulsion is out of the blood stream in $3\frac{1}{2}$ hours. When tagged with radioactive C^{14} the carbon can be detected in expired air within 2 minutes of being injected. 1 litre, carrying 3200 calories, can be given in half an hour, up to 5-6 g of fat per kg body weight per day is given. A glassful of the fat emulsion taken orally gives 1500 calories.

EARLY DEBRIDEMENT OF BURN WOUNDS

Pyruvic Acid—Dr SAMUEL C. HARVEY stated that pyruvic acid acts on the slough not digestively but rather as a physiological accelerator of the normal process of autolysis and separation.

Streptokinase and Streptodornase—Dr WILLIAM S. TILLET said that the effects of these enzymes are proportional to the amount of substrate against which they are active. Streptokinase is active against fibrin and globin, streptodornase against nucleotides, which form most of the solid component of pus. Both need serum for activity, this is absent in dry sloughs. Both cause proteolysis and liquefaction. They are not effective against collagen. The extensive slough of a burnt leg was "cross hatched" by incision, and the enzymes

were applied for some hours daily 20,000 units of streptokinase and 7000 units of streptodornase were applied each day, and the slough separated in 10-14 days. The raw area was then ready for grafting, the graft was a 75% "take," compared to a 50% take on the raw area on the control side. There have been no local or general toxic effects. Collagen and fibroblasts are not in the spectrum of these enzymes.

Collagenase—Dr. ALTMAYER has studied collagenases from three sources: clostridia, gram-negative bacilli, and vegetable compounds. For slough removal the chief need is a collagenase, since 70% of skin sloughs is collagen. The collagenase from clostridia (*Clostridium histolyticum*) and that from gram-negative bacilli accelerates the separation of sloughs, but less so than the collagenase from the vegetable compound. Application of this substance to experimental sloughs caused the sloughs to separate so rapidly that in 20 hours they could be wiped off, but there were severe reactions in the surrounding viable tissues. The problem now is to find the proper dosage of this extract, and the means of protecting normal tissues when it is used.

PLASTIC REPAIR OF SEVERE BURNS

Dr. J. BARRETT BROWN said that local technique is not as important as being kind, gentle, and clean in the treatment. He showed a number of slides demonstrating the excellent results that follow early grafting with good technique. Slides were also shown to illustrate the value of homografts as a temporary cover while the metabolic imbalance is corrected. Dr. Barrett Brown mentioned the risk of infection of dermatome donor sites, especially when the patient is in a state of metabolic imbalance. He believes that saline baths have a valuable place in treatment of the healing phase of extensive deep burns.

Dr. SUMNER L. KOCH showed slides illustrating the many and difficult problems in deep burns of the hand. Sloughs were generally removed in the second week under a tourniquet, a free graft cover was then given even when tendon and bone were exposed. In such deep burns the thin primary cover was later replaced by flaps of skin and fat under which the tendon, nerve, and bone grafts might be done.

DISASTER PROBLEMS OF BURN CARE

Dr. THOMAS G. BLOCKER, jun. pointed out that in mass disasters it is impossible to provide treatment by accepted standards, but preparation and planning are needed. He drew attention to the multiplicity of lesions in most disaster casualties, to the multiplicity of sources of trauma, and to the serious adverse effects of ionising radiation on the course of burns and soft tissue injuries. He believes that there is need for criteria by which the greatest proportion of patients can be saved. As to local treatment, the average doctor still cannot apply pressure dressings safely and properly, he has seen many examples of peroneal and ulnar nerve palsy following application of such dressings to burnt limbs. He believes that the best local treatment is by exposure. With this treatment fewer patients need grafts, there are fewer complications, and there is earlier ambulation and better morale throughout. He would recommend its use for A bomb burns caused by flash, affecting face or perineum, or one side (not the whole circumference) of a limb. The need for training more surgeons in methods of management is urgent. Finally he recommended five things in plans for these disasters: (1) concentration of treatment on patients with a chance of useful survival, (2) standardisation of methods at a lower level than the peace-time ideal, (3) the making of stock piles of essential medical equipment, (4) the issue of plans of treatment of early phases of burns to all physicians, and (5) establishment of burns centres.

Triage and Evacuation—Colonel PAUL HAYES said that estimates of A bomb casualties vary from 10,000 to 50,000 per bomb (10,000 if warning is good). Casualties are expected to be distributed as follows: blast 85%, heat 20%, radiation 15%. In an air burst all may be presumed dead within a radius of half a mile. The zone 1-2 miles beyond this will provide most of the severe injuries, and the zone beyond this again, the greatest number of minor injuries, especially flash burns. Ideal treatment will be impossible, but it is worth remembering the army maxim—"P P P" (prior planning pays). These medical plans "are not to be at sacrifice to the combatant services' ability to accomplish their mission."

Civil Defence Planning—Dr. NORVIN C. KIEFER said that casualties could be expected to be reduced by at least 50% if a few minutes' warning were given, and if there were a plan of protection of which the population was informed. Outside aid would be needed in targets within a few hours of their being hit. This aid would be of two types: (1) mutual aid from the immediate vicinity, the personnel acting according to a pre-arranged plan, and (2) mobile support, with police, fireworkers, doctors, and other teams from distant places. With an A bomb on Chicago surgical teams might be called on to come by air from as far away as Texas.

THE DISPLACED REGISTRARS

From Hospital to Practice ?

A TALBOT ROGERS

M.B. Lond.

FIVE years ago, when the war was ending, hopes ran high for the rehabilitation and expansion of our hospital services, and it did not seem unreasonable to encourage many of the doctors returning from the Services, to take up posts as registrars and train themselves for careers in an expanding specialist field. The establishment of registrars in teaching and other hospitals was then stepped up and has not since been reduced, even though signs became apparent long ago that we had many more men in specialist training than we could really absorb into consultant posts.

Now suddenly, and probably inevitably, drastic action has been taken. The planners have, in effect, admitted their mistake: they have suggested a future establishment of trainees which will prevent too many from wasting their years preparing for posts they will never achieve. But by so doing they have created a new situation which itself needs analysis and positive and intelligent planning if further frustration and chaos are to be averted.

IMPLICATIONS OF THE REDUCTION

The immediate result of the reduction in registrar establishment will be that some 1200 doctors in England and Wales with at least five years' postgraduate training, and often more, will be without posts when their present contracts expire. Their absorption into alternative posts will be a formidable problem. It will be no less of a problem to find ways whereby their present hospital duties can be performed when they are gone.

But this is not the whole story. The new establishment allows of the appointment each year of some 550 registrars (1100 spread over two years) of whom 200 each year will become senior registrars (800 spread over three years) and 150 will eventually find posts each year as consultants. This means that of the 550 hopefuls who each year achieve the rank of registrar (presumably after each has already done some two or three years' postgraduate hospital practice) 400 will not

grafting, of those with pressure dressings 27 needed grafting. None of the exposed patients had fever for 1-6 weeks, 34 of the patients treated with dressings had such a fever, and 5 of this group had streptococcal rashes, which were entirely absent from the exposed group.

Mr Wallace said that the exposure method is used by him as a means to an end—this end is to obtain a dry skin with maximal preservation of the skin's natural property of resistance to infection. He believes that a dry skin could probably also be obtained by an absorptive dressing. In his view the term "pressure dressing" is wrong, it should be replaced by the term "absorptive dressing." The two methods—exposure and absorptive dressings—are complementary rather than mutually exclusive. There are indications for the use of each.

INFECTION IN SEVERE BURNS

Mode of Infection and its Control—Dr LEONARD COLEBROOK, F.R.S., reviewed his very extensive experience while in charge of the M.R.C. burns units in Glasgow and Birmingham. The Glasgow burns were treated largely without antibiotics.

"The bacterial factor is the biggest in severely burnt patients." 90% of severe burns are complicated by infection, which postpones grafting and healing and causes unnecessary disability and unnecessary deaths. The tradition that in severe burns infection is inevitable is wrong, infection can be avoided. Today many cases of 60-70% body surface burns recover. Dr Colebrook reserved his judgment of the exposure method of treatment.

In Birmingham the policy was to regard all burns as liable to infection and needing treatment under a microbe proof barrier. This meant doing all dressings in a room with sterile air, and the use of topical penicillin. Dr Colebrook showed slides demonstrating relatively simple air conditioning apparatus, whereby an effective rate of air replacement from above down at 20-30 replacements per hour ensures a virtually sterile environment within the dressing room. The value of this sterile air has been difficult to assess, because a strict dressing technique and topical penicillin were used concomitantly. But the overall effect of these three factors was most striking. Thus, in Glasgow, without the dressing room, the infection rate with haemolytic streptococci was 30%, at Birmingham it was less than 5%. At Birmingham, too, many burns were kept completely sterile for 2-3 weeks. The average stay in hospital has been reduced by 50%. Clinically pain has been largely eliminated, and throughout treatment the morale of patients is good.

Dr Colebrook made a special plea for the establishment of burns centres in all large cities. About 100 beds per 1,000,000 population are necessary in England, in the U.S.A. burns are about twice as common, and 200 beds per 1,000,000 are probably necessary. He also drew attention to the possible conversion, for war purposes, of ambulances into mobile dressing rooms with sterile air produced by air conditioning at a high rate of air replacement. Another urgent need is the determination of a simple dressing (to be left on for a week) for hand and face flash burns.

Dr Colebrook declared that, in the event of mass casualties, streptococcal infection might again be seen in its old, dangerous, and epidemic form. Our present relative freedom is due to penicillin, to small numbers, and to conditions of treatment which could not be expected to prevail with mass casualties.

Antibiotic Therapy—Dr WILLIAM A. ALTEMEIER said that the majority of U.S. doctors prefer systemic to topical penicillin. Each antibiotic has a limited antibacterial spectrum. Penicillin has the widest range,

chloramphenicol the next widest, and then 'Auroomycin' and 'Terramycin'. Terramycin is effective against the highest percentage of cocci and gram negative bacilli, this is to be expected since it has been used only for a short time. Antibiotics are only a temporary measure in the control of infection in deep burns, these need surgical removal of the sloughs and a graft cover.

NUTRITIONAL CARE

Burn Anæmia—Prof G. WATSON JAMES outlined the biochemistry of the formation of hæmoglobin from a globin and from an iron containing hæm fragment. On breakdown the iron is retained by the body, the pigment excreted. The progenitor of the red cell is the site of the synthesis of hæm and globin into hæmoglobin. The resources for this are brought to the cell by the plasma. If the plasma protein (including glycine) is low there is normoblastic arrest. Any disturbance of porphyrin metabolism probably indicates severe disorder of red cell metabolism. He drew attention to the large amount of red cell mass that disappears after the dressing of extensive burns. In burn anæmia the hæmoglobin tends to settle at about 8-10 g per 100 ml. He concluded that the anæmia requires, for its radical treatment, the removal of dead tissue and healing by grafts.

Nutritional Care—Dr STANLEY M. LEVENSON spoke of the adverse effect on nutrition of combined radiation and thermal damage. Routes of feeding are by mouth, stomach, jejunum, or vein. Optimal amounts have not yet been determined, but high intake in the first week is always beneficial. The most useful diets are liquid, given as regular small feeds, with a calorie content of 3500-5000 and protein totalling 100-250 g. (When milk is the major protein source, there may be danger of calculi.) A thin plastic nasal tube may be left for up to 5 months, with weekly removal for cleaning, this permits administration of protein in the form of unpalatable liver feeds. 20% of calories should be from fat.

Dr FREDERICK J. STARE declared "I do not know what an adequate caloric intake for a severe burn is." A fine emulsion of coconut oil, in addition to providing calories, confers efficiency of utilisation on other elements in the diet. The average particle is $1\frac{1}{2}\mu$, none is larger than 3μ . With oral administration all the fat is absorbed, none is recovered in the faeces. The emulsion is palatable and can be used as a solvent for vitamin K. (When so combined and given intravenously, it can correct the effects of dicoumarol in 12-24 hours.) The emulsion is out of the blood stream in $3\frac{1}{2}$ hours. When tagged with radioactive C^{14} the carbon can be detected in expired air within 2 minutes of being injected. 1 litre, carrying 3200 calories, can be given in half an hour, up to 5-6 g of fat per kg body weight per day is given. A glassful of the fat emulsion taken orally gives 1500 calories.

EARLY DEBRIDEMENT OF BURN WOUNDS

Pyruvic Acid—Dr SAMUEL C. HARVEY stated that pyruvic acid acts on the slough not digestively but rather as a physiological accelerator of the normal process of autolysis and separation.

Streptokinase and Streptodornase—Dr WILLIAM S. TILLET said that the effects of these enzymes are proportional to the amount of substrate against which they are active. Streptokinase is active against fibrin and globin, streptodornase against nucleotides, which form most of the solid component of pus. Both need serum for activity, this is absent in dry sloughs. Both cause proteolysis and liquefaction. They are not effective against collagen. The extensive slough of a burnt leg was "cross hatched" by incision, and the enzymes

were applied for some hours daily 20,000 units of streptokinase and 7000 units of streptodornase were applied each day, and the slough separated in 10-14 days. The raw area was then ready for grafting, the graft was a 75% "take," compared to a 50% take on the raw area on the control side. There have been no local or general toxic effects. Collagen and fibroblasts are not in the spectrum of these enzymes.

Collagenase—Dr ALTEMEIER has studied collagenases from three sources: clostridia, gram negative bacilli, and vegetable compounds. For slough removal the chief need is a collagenase, since 70% of skin sloughs is collagen. The collagenase from clostridia (*Clostridium histolyticum*) and that from gram negative bacilli accelerates the separation of sloughs, but less so than the collagenase from the vegetable compound. Application of this substance to experimental sloughs caused the sloughs to separate so rapidly that in 20 hours they could be wiped off, but there were severe reactions in the surrounding viable tissues. The problem now is to find the proper dosage of this extract, and the means of protecting normal tissues when it is used.

PLASTIC REPAIR OF SEVERE BURNS

Dr J BARRETT BROWN said that local technique is not as important as being kind, gentle, and clean in the treatment. He showed a number of slides demonstrating the excellent results that follow early grafting with good technique. Slides were also shown to illustrate the value of homografts as a temporary cover while the metabolic imbalance is corrected. Dr Barrett Brown mentioned the risk of infection of dermatome donor sites, especially when the patient is in a state of metabolic imbalance. He believes that saline baths have a valuable place in treatment of the healing phase of extensive deep burns.

Dr SUMNER L KOCH showed slides illustrating the many and difficult problems in deep burns of the hand. Sloughs were generally removed in the second week under a tourniquet, a free graft cover was then given even when tendon and bone were exposed. In such deep burns the thin primary cover was later replaced by flaps of skin and fat under which the tendon, nerve, and bone grafts might be done.

DISASTER PROBLEMS OF BURN CARE

Dr TRUMAN G BLOCKER, jun., pointed out that in mass disasters it is impossible to provide treatment by accepted standards, but preparation and planning are needed. He drew attention to the multiplicity of lesions in most disaster casualties, to the multiplicity of sources of trauma, and to the serious adverse effects of ionising radiation on the course of burns and soft tissue injuries. He believes that there is need for criteria by which the greatest proportion of patients can be saved. With an A bomb on Chicago surgical teams might be called on to come by air from as far away as Texas.

THE DISPLACED REGISTRARS

From Hospital to Practice ?

A TALBOT ROGERS

M B Lond

FIVE years ago when the war was ending, hopes ran high for the rehabilitation and expansion of our hospital services, and it did not seem unreasonable to encourage many of the doctors returning from the Services, to take up posts as registrars and train themselves for careers in an expanding specialist field. The establishment of registrars in teaching and other hospitals was then stepped up and has not since been reduced, even though signs became apparent long ago that we had many more men in specialist training than we could really absorb into consultant posts.

Now suddenly, and probably inevitably, drastic action has been taken. The planners have in effect, admitted their mistake: they have suggested a future establishment of trainees which will prevent too many from wasting their years preparing for posts they will never achieve, but by so doing they have created a new situation which itself needs analysis and positive and intelligent planning if further frustration and chaos are to be averted.

IMPLICATIONS OF THE REDUCTION

The immediate result of the reduction in registrar establishment will be that some 1200 doctors in England and Wales with at least five years' postgraduate training, and often more, will be without posts when their present contracts expire. Their absorption into alternative posts will be a formidable problem. It will be no less of a problem to find ways whereby their present hospital duties can be performed when they are gone.

But this is not the whole story. The new establishment allows of the appointment each year of some 550 registrars (1100 spread over two years) of whom 200 each year will become senior registrars (600 spread over three years) and 150 will eventually find posts each year as consultants. This means that of the 550 hopefuls who each year achieve the rank of registrar (presumably after each has already done some two or three years' postgraduate hospital practice) 400 will not

become consultants, and each year 400 will be seeking alternative employment

Seen in this light, the present suggestion of directing some of the displaced registrars to specialist service in the Forces or in the Colonial Medical Service clearly provides no answer to the long term problem. Where, then, can these men go? Can they be satisfactorily absorbed into general practice? It is quite plain that under present conditions they cannot. The suggestion fails at once on the score of numbers alone. There are between 18,000 and 19,000 doctors in general practice in England and Wales (about 17,000 principals and perhaps 1700 assistants). Few of them wish, or are able, to retire early. The numbers of new practitioners needed to replace those who do retire or who die is unlikely to exceed 500 a year, and the displaced registrars will not be the only candidates for these 500 places. They will have as rivals all those of their colleagues who have never aspired to registrar status, or who have decided as soon as their first postgraduate year was over that general practice was their métier and that the sooner they entered it the better. And as things are now it will often be the younger man with fewer commitments and greater readiness and opportunity to serve an apprenticeship as an assistant that will be more easily placed in practice.

Could not this annual figure of 500 places be stepped up perhaps with benefit to the underdoctored areas? It might be were it not for two difficulties: first, that of finding suitable premises from which the doctor could practise, and secondly, that of paying for his services. The first difficulty will remain as long as housing shortages persist and health centre construction is deferred, the second as long as the present methods of computing and distributing the practitioners' pool remain unaltered. This central fund does not vary in size with the number of practitioners in the service. Every extra doctor joining the medical list makes one more to share a total financial allocation which no practitioner regards as adequate even for the present number. So if general practice is to be the destination of an appreciable proportion of the displaced registrars, new money will have to be found to pay them.

With the present completely separate organisation of hospital and general medical services, and with the tendency, too, for the hospital authorities to exclude the general practitioner from any but a most attenuated participation in the work of the hospitals, the ex-registrar would have difficulty today in finding a place in general practice where he would feel able to use to advantage the special knowledge and experience gained in his costly postgraduate years.

Does this, then, make nonsense of one of the Minister's suggestions for meeting the staffing difficulty in which regional boards may find themselves through the withdrawal of the registrars' services—namely, that

boards may appoint a suitably experienced general practitioner (normally one with a higher qualification and experience as a senior registrar or registrar) on a part time basis to act as a clinical assistant. This is intended as a long term method of meeting staffing difficulties in the senior registrar field, and has the advantage of providing a valuable link between the general practitioner and the hospital services. In making appointments of this kind it will be necessary for boards to satisfy themselves not only that the practitioner has the experience and qualifications required, but also that his commitments in general practice will not prevent his devoting the time needed to carry out the duties of the hospital post.

It does, if all is left to a vague policy of laissez faire, for the registrar will then be hard pressed to find a place anywhere in general practice, let alone somewhere where a hospital appointment suitable to his special training is also available. But given a co-ordinated policy between the regional hospital boards, the executive councils, and

the local medical committees, the Ministry's proposal could provide a method of entry into practice which would at the same time be to the advantage of the registrars, the hospitals, and general practice.

PLAN FOR CO-ORDINATION

The initiative in this matter must lie with the regional boards. There is the chief problem—that of ensuring that the work of the hospitals continues when the registrars are gone. There, too, is the chief moral responsibility for seeing that all that can be done is done to help the men who have in their years of training helped the hospitals so much.

With the reduced establishment of registrars it will obviously now be necessary for the regional boards and boards of governors to re-examine every present post and determine whether it shall still remain a registrar appointment. Many of the posts which give less favourable opportunities for teaching or for gaining specialist experience will no longer be classified as registrar appointments. Where this is so, and the duties of the post cannot be absorbed satisfactorily by the remaining establishment, the regional boards should consider whether they could obtain the extra help they need by creating one or more part time clinical assistantships. If so, they should consult with the local medical committee, which alone knows of the potentialities of general practice in the area and the extent to which the commitments of the local practitioners allow of their participating in hospital work. Possibly among the practitioners already established there may be one suitable to take on the required duties. More probably it will be necessary to advertise the post with a view to finding someone of registrar status to fill it. In this case the regional board should decide the number of weekly sessions it is prepared to offer, and should state the remuneration this work will carry. The local medical committee will be able to advise on the opportunities the doctor appointed will have of supplementing his hospital work by general practice, and the limit that should be put to his general practitioner work bearing in mind his hospital commitments.

Quite apart from the definite attraction of association with the local hospital, the fact that even at the start the doctor would not be a total liability to any practice he joined, but would carry with him an income in his own right, should make it easier for him to find a place as partner or assistant in an established practice. Moreover, nowadays quite a number of small practices are falling vacant in which the numbers are too small to justify the appointment of a successor, and these practices are dispersed. Such a practice could often be quite satisfactorily taken over by a man with a part time hospital appointment, as a nucleus on which he could build. Then again there are areas where local conditions (as in a growing town) would make it possible for a doctor, even when starting on his own, to build within a reasonable time a large enough practice to provide, with his hospital salary, a passable income.

Nevertheless some of the practitioners appointed will need to be subsidised beyond their hospital stipend while waiting for opportunities to enter practice, or for their practice to grow. If such subsidy is necessary, it must come from the regional board, for this is not a charge that the practitioners' present fund could reasonably be expected to bear.

NEED FOR A NEW APPROACH

Admittedly this is a revolutionary approach to entry into practice, but the situation facing the registrars is one in which no orthodox approach offers hope of relief. The essence of the scheme is that the onus of making the posts and of finding the money to pay for

them is placed on the regional hospital boards. More men will be placed in practice, but the total pool for practitioner remuneration will be augmented by money coming from hospital sources. Much, if not all, of this new money will come from sums originally set aside for paying registrars.

Among the matters that remain to be decided are terms of service and the amount of remuneration, the place the practitioner should occupy in the hospital hierarchy (would it be that advanced in the Oxford plan for the "area department team" ?), the types of specialty that could be covered (some help might be obtained from the recent circular on *sumo* posts), whether the appointment should be permanent from the start or only after experience has proved the practitioner's suitability for his dual role, and whether, at the practitioner's request, the type and extent of his hospital duties could be varied, the better to fit with his increasing commitments in practice.

These details can no doubt be settled at the proper time. At present it is important only to know whether the principle underlying this scheme is acceptable. If it is, and if it is thought worth a trial, the regional boards will need to act throughout in concert with the local medical committees and the executive councils. There are still few places in the country where machinery for close liaison between these bodies exists. For combined action such machinery should be set up without delay, for there is much to be done, and the sands, like the registrars' contracts, are fast running out.

FELLOWSHIP FOR FREEDOM IN MEDICINE

ADDRESSING the annual general meeting of the Fellowship on Nov. 18, Lord HORDER said that the tasks it has set itself were (1) to restore the morale of the profession, (2) to protect and encourage private practice, (3) to disillusion the public about the National Health Service in the face of political propaganda, (4) to call attention to its inherent defects, and to examples of maladministration and extravagance, (5) to advise practical remedies for the deficiencies of the Act, and (6) in particular, to permeate the British Medical Association with the ideals of the Fellowship. In every one of these respects, it had made progress: the morale of the profession had risen, the press and public were becoming critical of the service, and even of its underlying principles, and instances of extravagance and maladministration were brought to light every day. Lord Horder then defined the policy of the Fellowship on a number of other questions. It supported the claim of the B.M.A. for a just settlement of the betterment factor and it supported the British Medical Guild as an instrument which would enable the profession to withdraw from the service if necessary. It sympathised with the efforts of general practitioners to preserve their hospital facilities, and it was again "the closed shop." He likened the dream of the Welfare State to a phantasmagoria—"a series of optical illusions arranged for public display"—and said that the present situation would not improve until we awoke from this dream. He was not worried about membership—every cause had a ceiling, and perhaps 3000 was the Fellowship's ceiling. In any case, it had become the focal point of resistance to deteriorating standards, loss of freedoms, and personal frustration: its influence would inevitably increase.

Before the Chairman's address, Dr. A. G. E. BREACH defined the ways in which the Act should be amended. The powers of the Minister should be reduced, he said, there should be an independent court of arbitration to which either party could refer a dispute, and the penalising clauses of the Act ("an amateur attempt to short-cut the law") should be abolished. Hospitals should receive block grants to spend at their discretion, medical staff committees should enjoy a statutory right to submit advice, and the Minister should set up a central appeal mechanism for grading. Dr. Breach then turned to private practice and suggested that doctors should be able to regain the ownership of the

goodwill of their practices. There should be free drugs for private patients, grants in-aid for those who chose private beds, and facilities for anyone to "contract out" of the service and receive compensation from the State. He anticipated that the Government would require a guarantee that those who "contracted out" would not, at some future date, become a burden on the State, and he was therefore looking for an insurance company which would provide cover against all forms of sickness at a fixed premium, without a medical examination. He went on to say that the fellowship sought to promote its ideas by "introducing its leaven into the mass of the B.M.A." Its members were already playing a prominent part in B.M.A. activities and committees.

Dr. G. J. V. CROSBIE, another member of the executive, said that the general practitioners were losing touch with hospital medical officers. Practitioners should not only be provided with the full range of diagnostic facilities but should also be admitted to hospital practice. He then introduced Dr. T. W. MORGAN, of Kingston, who was loudly cheered when he described the action taken by him and his colleagues to retain the use of the Kingston Victoria Hospital, the meeting adopted a resolution in support of this hospital and of any others in a like situation.

Dr. A. D. KELLY, assistant secretary of the Canadian Medical Association, was asked to describe the insurance scheme which some divisions were offering the public as an alternative to commercial insurance or a State service. These schemes he said, covered 500,000 persons against all forms of sickness without any medical examination. Doctors received a proportion of the pool corresponding to the premiums paid into it by their patients. In his opinion, it was preferable to try and modify government policy before it had been translated into law.

Medicine and the Law

A Question of Diagnosis

As there seems sometimes to be an impression that medical practitioners guarantee infallibility, the judgments of the House of Lords in *Whiteford v. Hunter*, though they may induce a natural sympathy for the unsuccessful appellant, are professionally reassuring.

The facts of the case, which have already been recorded,¹ are briefly as follows. Mr. Whiteford, an American engineer, consulted a London surgeon, Mr. J. B. Hunter, in March and April, 1942. He alleged that his condition was then diagnosed as a cancerous growth in the bladder and that he was warned not to expect to live much longer, the growth being so far developed that nothing could be done for him. Thereupon Mr. Whiteford closed down his practice, gave up all his concerns in England, and went home to America to die. On his taking further advice in New York, Dr. Benjamin Barringer, emeritus urologist at the Memorial Hospital in that city, established the absence of cancer, found the patient to be suffering from chronic cystitis and a considerable bladder diverticulum, and cured him. Mr. Whiteford, suing Mr. Hunter for damages for negligence, was awarded £6300 damages by Mr. Justice (now Lord Justice) Birkett. The Court of Appeal allowed Mr. Hunter's appeal and on Nov. 16 the House of Lords upheld the Court of Appeal.

Mr. Whiteford's case was founded not so much upon negligent diagnosis as upon the criticism that, there being a close resemblance between real and simulated cancer, a diagnosis of cancer should not be accepted without a pathological examination. A plaintiff who claims damages for negligence must give particulars of the negligence which he alleges. The two specific allegations which influenced the court of first instance were, according to Lord Porter's opinion in the House of Lords, (1) the

omission to use a cystoscope before opening the bladder, and (2) the omission to take a specimen of the growth in order to make a microscopical test of the presence or absence of cancer. Dr Barringer, giving evidence on commission for the plaintiff, stated that there was no difficulty or danger in either of these operations.

Lord Porter observed that all the medical witnesses in this country asserted that it was contrary to approved practice to use a cystoscope in cases of acute urinary retention, when the bladder was drained and collapsed, they said, it was difficult, if not impossible, to use a cystoscope effectively unless it was an instrument of the flushing type. Mr Hunter did not possess such an instrument, it was rare in this country at the material date. As regards the growth, Mr Hunter had spoken of "an indurated mass covered with thickened mucous membrane abnormal in colour." Apparently Dr Barringer, examining Mr Whiteford in August, 1942, did not have in mind the condition found by Mr Hunter in the previous April, when the bladder was opened. The circumstances in which Dr Barringer opened the bladder were very different from those subsisting when Mr Hunter made his diagnosis. Even if Dr Barringer's evidence

were accepted in full, said Lord Porter, no specimen could have been taken unless the cystoscope was fitted with a rongeur attachment, witnesses had proved that such an instrument was in 1942 rare in England and was not then possessed by Mr Hunter. The two specific allegations of negligence having thus been dealt with, Lord Porter reaffirmed the general statement of the law which Lord Justice (now Lord) Maugham made in 1935 in *Marshall v Lindsey County Council*: "A defendant charged with negligence can clear himself if he shows that he has acted in accord with general and approved practice." Mr Hunter gave evidence in the trial court that his action did so conform, and two eminent surgeons had testified in support of his statement.

Mr Hunter's vindication is a satisfying success for the legal experts whom a medical defence society can bring to the help of a defendant practitioner. In this litigation there was, through no fault of theirs, an adverse finding of fact in the court of first instance. To controvert and displace an adverse finding of fact, as Mr Hunter's counsel managed to do in the Court of Appeal, is a task of known difficulty. The Medical Defence Union can be congratulated on the result.

Disabilities

53 MINER'S NYSTAGMUS

On leaving school in April, 1914, my real desire was to be a farmer, I have always loved the country and still do. I suppose it would be because I thought I would make a little more money, and that my father and grandfather had been miners, that I went to the colliery. It was in the August of that year (the critical month in the history of this country), after working on the pit head for a few weeks, that I went to the lump cabin, armed with a note signed by the colliery manager, and demanded a lamp. While I was thrilled at the adventure of descending the mine, still it was not my desire—the open field would have suited me much better.

I am not a tall man by any means, but at that time I was small—so small that, as I walked along the tub way, I had to keep lifting my oil lamp up to prevent it from knocking against the rails and going out. (The tubs—small wagons holding 8 cwt of coal—run along this little two foot gauge railway.) After learning to harness and yoke a pony, I was taught to ride the ladders—iron shafts ending in a hook to fix on to the tub—and thus became a driver. Time went on, and at 18 I became a putter, taking tubs to and from the hewer, a much more strenuous job, for which I was paid by the score of tubs put. This meant, besides lots of other things, competition with other putters.

In 1926 there was a spell on the dole for a month or so, my colliery having closed down, and after that I became a hewer with a hand pick. This again was piece work and meant competition with other men. One must get as much as the next man, unless there is a vast amount of difference in the nature of the coal, no matter what advantage he may have in size and strength. Looking back, I can see that it was the constant strain of working in a poor light, and striving to produce the same as other men in my district, that began the trouble with my eyes. I don't recall any pain then, but I remember that after only a year of face work, I often had to put my hand out and touch a prop to steady myself while walking in by to the place where I was working. By this time I was married with a small family, which added to my responsibilities. The struggle through the 1926 strike, and extremely hard times after, had all meant nervous strain, and as the years went on my eyes became gradually worse. Many times I thought of going to the doctor about them, but the prospect of a small compensation or sick pay was not encouraging, so for over twenty years I went on as I was.

At home, and in any public buildings I had (and still have) to shield my eyes from the light, and in the pit the torture of a light in front got more acute. Later still I began to have a sensation of dizziness when stooping, sometimes even when looking down at my plate while sitting at the table. What made me go to the doctor eventually—in April, 1949—were the severe pains I began to get in the back of my head. Even while I was in bed these pains were frightening, and besides I began to stumble when rising to my feet.

My doctor wrote a note to an eye infirmary, but it was not until November that I was sent for to be examined. I came back with a letter from the surgeon, and after this my doctor's certificate (I was off work at this time with my eyes) said that I had nystagmus. At once the National Insurance authorities sent me to their doctor, who disagreed about my case, so I couldn't claim industrial disease benefit. About three weeks later I was sent by the insurance authorities to a specialist, and he also was not satisfied. It seems that, though I had many of the symptoms of the disease, they couldn't at that moment find any oscillation. Eventually, after a few weeks, I was sent to a lady doctor, who evidently decided I had nystagmus, for the following week I received a little over £8 from the National Insurance—the difference between sick pay and industrial disease benefit for the few weeks I was off at the end of last year.

After I had been off five weeks I asked my own doctor, if I could go back down the mine. He was surprised, but said I could try, and I have been at my old job at the coal face ever since. I have still got the trouble, as bad as ever, but I have learnt that resting when I can helps me to manage my work. Nothing else eases my head pains, and if I couldn't rest for a day or two now and again I should have to leave my work altogether.

A few weeks ago I received a kind invitation from a medical college to be examined for the cause of nystagmus research. It was rather strange to have an electric cap put on my head, and someone in the next room studying so it seems, the inside of my head. And on my second visit the questions I was asked were innumerable—two hours of questioning. But I didn't mind because I was resting my eyes, and my full pay was assured. Then I was invited to attend an eye infirmary, and answered more questions, this time my wife was asked too, and she answered questions on our home life. In all this I was really treated like a gentleman and not just one of a mob.

I go my way trusting in God, working, resting when I can, and not worrying overmuch.

Parliament

Transferred Patients

IN the House of Commons on Nov. 13, Mr EDWARD HEATH called attention to the problems which arise when a doctor's list of patients has to be reduced. In the early days of the health service nothing had been done to implement the decision that lists should not exceed 4000, and accepted patients had assumed that they were on the selected doctor's list for good. Early this year the Ministry of Health, in agreement with the medical profession, decided that lists must be reduced. Doctors with an excess of patients were asked to take a partner or assistant, or indicate the names of the patients who were to be removed from their list. If a doctor declined to do either of these things—and he had the right to decline—the local executive council took the matter in hand themselves. They had discretion as to the method they used, but the Ministry had produced a model allocation scheme.

Turning to the example in his own constituency of Bexley, Mr Heath related how Dr Green¹ who had surgeries in both Bexley Heath and Erith, had over 5000 patients. As Dr Green refused to take an assistant or partner, or to name the patients to be taken off his list, the executive council had drawn an ellipse round the area which included both the surgery and branch surgery of Dr Green so that it would take in the maximum of 4000 patients. A notice had been sent to every patient living outside that area informing them that within seven days they would be struck off Dr Green's list and must find another doctor among those on the Post Office list for the borough. Mr Heath did not object to the reduction of the list, but to the way it had been done. The general turnover of a doctor's list, he understood, was between 300 and 600. Why Mr Heath asked, could not the list be closed and allowed to reduce itself to about 4200 in about eighteen months? He objected strongly to the geographical method instead of patients who had joined the list last should be the first to go. Seven days' notice, he declared, was callous. Patients who wished to change their doctor had to give three weeks' notice. Again was it too much to ask that the executive council on striking a person off a doctor's list should provide him with a list of the doctors whose lists were not yet full?

Mr ARTHUR BLENKINSOP, parliamentary secretary to the Ministry of Health, did not think that the wording of the circular sent out in the Bexley and Dartford area was the best that could have been designed. It had always been the intention that a certain maximum number of patients on a doctor's list should be insisted upon in order to secure a proper service. No vacancies for new doctors desirous of entering the service could be provided unless some reasonable maximum figure on the individual list was fixed. Some members of the medical profession argued that 4000 was far too high. He appreciated that the reduction of lists caused hardship and a certain amount of ill-feeling among the patients concerned. The reason why lists were allowed to grow in the initial stages of the service was to be certain that families already on the lists were not ruled out. If Dr Green had tried to help the executive council, as most doctors had tried to do, in carrying out this general decision on limitation, a great deal of the difficulty which had arisen could have been avoided. Not having the assistance of the doctor the executive council took what Mr Blenkinsop regarded as on the whole a reasonable decision to try to rule out those patients who appeared to them to be farthest away from the doctor's main centre of practice. Any patients actually in receipt of treatment at the time would not be withdrawn from the list, and a patient excluded from a doctor's list could still get emergency treatment should the need arise before he managed to select another doctor. But Mr Blenkinsop agreed that it was a point whether or not seven days was sufficient notice. He also thought that executive councils should give patients a list of other doctors in the area rather than merely refer them to the Post Office list. After examining the case

as a whole Mr Blenkinsop did not feel that the strictures on the executive council were really justified.

Trade-union Membership

ON Nov. 14, Dr CHARLES HILL drew attention to Durham County Council's resolution requiring every member of their staff to produce evidence of membership of a trade union or professional association under threat of dismissal. He believed the decision to be wrong in three respects. It was damaging to a trade union or professional association to receive members under duress. Secondly, the local authority should employ the best qualified people whether they belonged to this or that organisation or not. Dr Hill also believed it to be wrong for a man's job to be at the mercy, not only of an employer, but also of a trade union. The B.M.A. he continued, was a voluntary body and its attitude was that no doctor should be required to join any body, not even the B.M.A. If any local authority offered an advertisement for the *British Medical Journal* requiring the applicant to be a member of the B.M.A., it would be rejected. In 1946 when the staff of a maternity hospital at Willesden were told to belong to a union or leave, the Ministry of Health sent out a circular which ran:

The Minister wishes to make it clear to all local authorities that he considers that their primary duty as health authorities is to maintain the efficient and smooth running of their health services and to ensure the welfare of the patients for whom they are responsible. All other considerations must in his view, be regarded as secondary and he trusts that local authorities will follow this principle in their administration. While the Minister is anxious that doctors, nurses and members of similar professions should join a trade union or appropriate professional association, he considers that this matter should not be determined by the unilateral action of local authorities.

Dr Hill asked the Minister to repeat this advice.

Dr H. B. MORGAN thought it reasonable to require an individual to join an organisation which might be a party in negotiations on conditions of employment. The Durham County Council were not telling the doctors that they must belong to the B.M.A. or the M.P.U., but they wanted to know that they were members of some representative organisation which could speak jointly for them and for other employees. Dr Hill interposed that negotiating machinery for the most part existed in the Whitley structure.

Mr BLENKINSOP said that the part of the 1946 circular which had been read to the House still represented the view of the Ministry of Health and indeed of the Government. They regretted the resolution passed by the Durham County Council. At the same time they were anxious that local authority and other employees in regular employment should join their respective trade union or professional body. They would certainly take the measures open to them—they were merely advisory—and draw the county council's attention to the circular issued in 1946, and the reply given in 1948 by the Minister of Health to a question in the House of Commons when he said:

I hope that persons employed in the National Health Service will be encouraged to belong to their appropriate organisations but it will not be a condition of employment and there will be no pressure upon anyone to belong to any organisation whether professional or trade union.²

The Doctor's House

IN the House of Commons on Nov. 16, Miss P. M. HORNSBY-SMITH called attention to the method of appointing doctors to the new London County Council estate, area of over 3000 houses known as St Pauls Cray. A large population was being transferred to the estate which gave scope for doctors to build up a practice. One would have expected these openings to be advertised, and that from the applications the Medical Practices Committee would select doctors to practise on the estate. During the past four months she had received protests against the active Communist activities of two of the four doctors appointed to a practice on this estate. She had therefore investigated the method of

¹ See *Lancet*, Nov. 18, 1950, p. 592.

omission to use a cytoscope before opening the bladder, and (2) the omission to take a specimen of the growth in order to make a microscopical test of the presence or absence of cancer. Dr Barringer, giving evidence on commission for the plaintiff, stated that there was no difficulty or danger in either of these operations.

Lord Porter observed that all the medical witnesses in this country asserted that it was contrary to approved practice to use a cytoscope in cases of acute urinary retention, when the bladder was drained and collapsed, they said, it was difficult, if not impossible, to use a cytoscope effectively unless it was an instrument of the flushing type. Mr Hunter did not possess such an instrument, it was rare in this country at the material date. As regards the growth, Mr Hunter had spoken of "an indurated mass covered with thickened mucous membrane abnormal in colour." Apparently Dr Barringer, examining Mr Whiteford in August, 1942, did not have in mind the condition found by Mr Hunter in the previous April, when the bladder was opened. The circumstances in which Dr Barringer opened the bladder were very different from those subsisting when Mr Hunter made his diagnosis. Even if Dr Barringer's evidence

were accepted in full, said Lord Porter, no specimen could have been taken unless the cytoscope was fitted with a rongeur attachment, witnesses had proved that such an instrument was in 1942 rare in England and was not then possessed by Mr Hunter. The two specific allegations of negligence having thus been dealt with, Lord Porter reaffirmed the general statement of the law which Lord Justice (now Lord) Maugham made in 1935 in *Marshall v Lindsey County Council*: "A defendant charged with negligence can clear himself if he shows that he has acted in accord with general and approved practice." Mr Hunter gave evidence in the trial court that his action did so conform, and two eminent surgeons had testified in support of his statement.

Mr Hunter's vindication is a satisfying success for the legal experts whom a medical defence society can bring to the help of a defendant practitioner. In this litigation there was, through no fault of theirs, an adverse finding of fact in the court of first instance. To controvert and displace an adverse finding of fact, as Mr Hunter's counsel managed to do in the Court of Appeal, is a task of known difficulty. Parliament

Transferred Patients

IN the House of Commons on Nov 13, Mr EDWARD HEATH called attention to the problems which arise when a doctor's list of patients has to be reduced. In the early days of the health service nothing had been done to implement the decision that lists should not exceed 4000, and accepted patients had assumed that they were on the selected doctor's list for good. Early this year the Ministry of Health, in agreement with the medical profession, decided that lists must be reduced. Doctors with an excess of patients were asked to take a partner or assistant, or indicate the names of the patients who were to be removed from their list. If a doctor declined to do either of these things—and he had the right to decline—the local executive council took the matter in hand themselves. They had discretion as to the method they used, but the Ministry had produced a model allocation scheme.

Turning to the example in his own constituency of Bexley, Mr Heath related how Dr Green,¹ who had surgeries in both Bexley Heath and Erith, had over 5000 patients. As Dr Green refused to take an assistant or partner, or to name the patients to be taken off his list, the executive council had drawn an ellipse round the area which included both the surgery and branch surgery of Dr Green so that it would take in the maximum of 4000 patients. A notice had been sent to every patient living outside that area informing them that within seven days they would be struck off Dr Green's list and must find another doctor among those on the Post Office list for the borough. Mr Heath did not object to the reduction of the list, but to the way it had been done. The general turnover of a doctor's list, he understood, was between 300 and 600. Why, Mr Heath asked, could not the list be closed and allowed to reduce itself to about 4200 in about eighteen months? He objected strongly to the geographical method, instead patients who had joined the list last should be the first to go. Seven days' notice, he declared, was callous. Patients who wished to change their doctor had to give three weeks' notice. Again was it too much to ask that the executive council on striking a person off a doctor's list should provide him with a list of the doctors whose lists were not yet full?

Mr ARTHUR BLENKINSOP, parliamentary secretary to the Ministry of Health, did not think that the wording of the circular sent out in the Bexley and Dartford area was the best that could have been designed. It had always been the intention that a certain maximum number of patients on a doctor's list should be insisted upon in order to secure a proper service. No vacancies for new doctors desirous of entering the service could be provided unless some reasonable maximum figure on the individual list was fixed. Some members of the medical profession argued that 4000 was far too high. He appreciated that the reduction of lists caused hardship and a certain amount of ill feeling among the patients concerned. The reason why lists were allowed to grow in the initial stages of the service was to be certain that families already on the lists were not ruled out. If Dr Green had tried to help the executive council, as most doctors had tried to do, in carrying out this general decision on limitation, a great deal of the difficulty which had arisen could have been avoided. Not having the assistance of the doctor the executive council took what Mr Blenkinsop regarded as on the whole a reasonable decision to try to rule out those patients who appeared to them to be farthest away from the doctor's main centre of practice. Any patients actually in receipt of treatment at the time would not be withdrawn from the list, and a patient excluded from a doctor's list could still get emergency treatment should the need arise before he managed to select another doctor. But Mr Blenkinsop agreed that it was a point whether or not seven days was sufficient notice. He also thought that executive councils should give patients a list of other doctors in the area rather than merely refer them to the Post Office list. After examining the case

as a whole Mr Blenkinsop did not feel that the strictures on the executive council were really justified.

Trade-union Membership

On Nov 14, Dr CHARLES HILL drew attention to Durham County Council's resolution requiring every member of their staff to produce evidence of membership of a trade union or professional association under threat of dismissal. He believed the decision to be wrong in three respects. It was damaging to a trade union or professional association to receive members under duress. Secondly, the local authority should employ the best qualified people whether they belonged to this or that organisation or not. Dr Hill also believed it to be wrong for a man's job to be at the mercy, not only of an employer, but also of a trade union. The B M A, he continued, was a voluntary body and its attitude was that no doctor should be required to join any body, not even the B M A. If any local authority offered an advertisement for the *British Medical Journal* requiring the applicant to be a member of the B M A, it would be rejected. In 1948 when the staff of a maternity hospital at Willesden were told to belong to a union or leave, the Ministry of Health sent out a circular which ran

"The Minister wishes to make it clear to all local authorities that he considers that their primary duty as health authorities is to maintain the efficient and smooth running of their health services and to ensure the welfare of the patients for whom they are responsible. All other considerations must in his view, be regarded as secondary and he trusts that local authorities will follow this principle in their administration. While the Minister is anxious that doctors, nurses and members of similar professions should join a trade union or appropriate professional association he considers that this matter should not be determined by the unilateral action of local authorities."

Dr Hill asked the Minister to repeat this advice.

Dr H B MORGAN thought it reasonable to require an individual to join an organisation which might be a party in negotiations on conditions of employment. The Durham County Council were not telling the doctors that they must belong to the B M A or the M P U, but they wanted to know that they were members of some representative organisation which could speak jointly for them and for other employees. Dr Hill interposed that negotiating machinery for the most part existed in the Whitley structure.

Mr BLENKINSOP said that the part of the 1946 circular which had been read to the House still represented the view of the Ministry of Health and indeed of the Government. They regretted the resolution passed by the Durham County Council. At the same time they were anxious that local authority and other employees in regular employment should join their respective trade union or professional body. They would certainly take the measures open to them—they were merely advisory—and draw the county council's attention to the circular issued in 1946, and the reply given in 1948 by the Minister of Health to a question in the House of Commons when he said

"I hope that persons employed in the National Health Service will be encouraged to belong to their appropriate organisations but it will not be a condition of employment, and there will be no pressure upon anyone to belong to any organisation whether professional or trade union."

The Doctor's House

In the House of Commons on Nov 16, Mrs P M HORNSBY SMITH called attention to the method of appointing doctors to the new London County Council estate, area of over 3000 houses known as St Paul's Cray. A large population was being transferred to the estate which gave scope for doctors to build up a practice. One would have expected these openings to be advertised, and that from the applications the Medical Practices Committee would select doctors to practise on the estate. During the past four months she had received protests against the active Communist activities of two of the four doctors appointed to a practice on this estate. She had therefore investigated the method of

¹ See *Lancet* Nov 18, 1950 p 592

their appointment and found that Dr J D Paulett was granted by the LCC a house compulsorily acquired from a private owner. Having got those premises he applied to the Medical Practices Committee saying that he had been granted the doctor's house on the estate and asked for permission to practise. At that time other doctors had submitted their names to the LCC as wishing to practise, but only the name of Dr Paulett appeared to have gone forward, and as there was only one applicant in the field the Medical Practices Committee had no option but to appoint him. One of the three other doctors who were later appointed also applied to the committee for permission to practise, saying he had premises and facilities given him by the LCC. Miss Hornsby-Smith urged that the position of the MPO was prejudiced when they had only one name submitted to them and when that applicant claimed that he had the premises and that virtually he was allowed to start up in practice. The LCC by deciding which doctors should be allocated a house from which to practise were in fact choosing the doctors on this estate and usurping the statutory right of choice of the MPO. She asked that applications by doctors wishing to practise in these areas should be submitted to the MPO who could then say to the local authority "we choose doctors A, B, and C, and we look to you to provide accommodation for them." Mr PERCY DAVIES: Is the hon Lady saying that these doctors were chosen because they were Communists? Miss HORNSBY SMITH replied that she thought the selection of names to go forward to the Medical Practices Committee showed signs of definite political prejudice.

Mr ARTHUR BLENKINSOP bitterly resented the manner in which the subject had been raised, especially the implicit suggestion that the political views of doctors should be taken into account on their appointment. The whole medical profession desired to have freedom for doctors to set up practice. On the broader issue raised, he continued, any doctor might apply to practise in an area, and could only be refused if the area was overdoctored. Vacancies were advertised only when a sitting doctor withdrew or where the area was underdoctored.

Dr CHARLES HILL thought this was an instance of a general difficulty underlying the machinery of the Medical Practices Committee. If a vacancy arose through the death or retirement of a doctor and it was decided to fill the vacancy, and the full procedure of advertisement and selection had been followed, then if a doctor—whether he was an applicant or not—had obtained by purchase or otherwise premises from which the practice was conducted, or the only appropriate professional premises in the area, it was difficult to make an effective choice of any other person. That was the difficulty which the Medical Practices Committee, with the co-operation of the medical profession, were trying to tackle. Whatever other issues might be involved in this case, there was, he urged, a general problem. It would be a pity, he thought, if the new National Health Service machinery were short-circuited by a local authority who named a doctor as tenant. He thought there was good reason for the LCC to follow another method to ask the official machinery to advertise the vacancy and to allot the house to the selected doctor. One general method should be adopted, approved by the Ministry of Health and under the supervision of the MPO, to avoid this instance of tenancy being the best part of the law.

Mr BLENKINSOP said he appreciated the points which Dr Hill had raised and the Ministry would be prepared to look into the question. What he resented so deeply was the implication that this was tied up with some preferential treatment for alleged Communists. There was certainly a problem in relation to doctors' premises, and he could give an assurance that the point would be considered in relation to the discussions which the Ministry were already having with the British Medical Association.

Penicillin (Merchant Ships) Bill

On Nov 14, Lord SHEPHERD moved the first reading of this Bill. Its purpose is to amend the Penicillin Act

so that penicillin can be used for the treatment of persons on board merchant ships which do not carry a doctor. Cases have occurred where members of the crew of a merchant ship suffering from an infected wound, for example, have not been able to have treatment with penicillin if there was no doctor on board. It is now felt that the experience gained in the use of penicillin makes it possible to define when it can and cannot safely be used. If the Bill is approved, advice on these lines will be included in the *Ship Captain's Medical Guide* which is carried on merchant ships in accordance with the Merchant Shipping Act, 1894.

QUESTION TIME

Incidence of Tuberculosis

Replying to a question Mr A BEVAN said that 52,041 cases of tuberculosis were notified in England and Wales in 1949. He thought that figure showed an increase. These increases were due to the fact that mass radiography was now being used. Although more cases of respiratory tuberculosis were being discovered—the increase in notifications being 5½%—there had been a decrease in deaths over the last five years of 12½%.

In answer to further questions he said that patients with early tuberculosis discovered by mass radiology tests were referred to a chest physician and treated according to their need and the facilities available. There was some delay in the provision of treatment, but fortunately the treatment which was being given was reducing the number of deaths. The general over all position was certainly improving. He agreed that the real problem was the shortage of nurses. That was the reason why he had circumscribed hospital authorities asking them to make beds available for this type of case in general hospitals. He had had an interim report, and there had already been a very large increase in the number of beds available. Annual returns as at Dec 31 last showed that the number of patients waiting for accommodation in tuberculosis hospitals and sanatoria was then approximately 11,000. He had been prepared to consider making use of the large number of beds available in Switzerland, but currency difficulties were involved. He would be able to give the House before long a report on the progress made in providing hospital beds for tuberculosis treatment in this country.

Increased Cost of Private Hospital Wards

In answer to a question Mr BEVAN stated that the increases for private ward treatment in the Merseyside hospitals, where the costs had increased by 100% from July, 1948, up to September, 1950, were partly due to increased costs and partly to the fact that the charge now covered the full cost in all cases.

Mr H D OAKSHOTT: As the use of private wards must relieve the pressure on public wards, will the Minister consider reducing the charges for private wards? Mr BEVAN: That would really mean that a larger number of people would be able to pay for beds at the expense of others.

Replying to Mr G H OLIVER, Mr BEVAN said if he was supplied with particulars of cases where admission to hospital was medically urgent and had been refused he would be glad to make inquiries. Mr OLIVER: Is the Minister aware that I have sent him particulars of a case where the patient after waiting for 11 months to enter a hospital was able to obtain admission as a private patient in less than 11 days?—Mr BEVAN: If the patient was not suffering from anything requiring urgent medical treatment no problem arises, but he had no right to go into hospital ahead of people in greater medical need. Mr OLIVER: But if the patient was not suffering from something requiring urgent medical attention why could he enter the hospital as a paying patient in under 11 days?—Mr BEVAN: I quite agree about that and I will investigate the matter if particulars are sent to me. I am far from satisfied with the way in which it is possible for doctors to get their private patients into hospitals.

Cost of N H S Prescriptions

Mr R H TURTON asked the Minister whether, in view of the evidence received from the Joint Pricing Committee for England that the average cost of prescriptions per person from Jan 1 to Sept 30 1949 was 11s 4½d, he was prepared to review the present dispensing capitation fee of 6s 6d.

paid to doctors who supplied medicines to patients on their National Health Service lists—Mr BEVAN replied "No, Sir. The figure quoted and the fee are not comparable. In addition to the fee pro rata payment is made to the doctors for certain individual items supplied."

Part-time Nurses

In answer to a question Mr BEVAN stated that the number of part time nurses had never been higher than the present total of 25,000. It was about 17,000 when the National Health Service began.

Imports of Aureomycin

In answer to a question Mr BEVAN stated that 140,075 grammes of 'Aureomycin,' apart from small quantities for sample and trial purposes, had been imported from the United States of America during the nine months ended Sept 30, 1950.

Food Allowances for the Tuberculous

In answer to Miss M. P. HORNBY SMITH, who asked why the priority ration of an extra ounce of cooking fat and bacon was no longer included in priority food rations granted to sufferers from tuberculosis, Mr MAURICE WEBB said in view of the present levels of the bacon and cooking fat rations his medical advisers were satisfied that there was no need to continue these extra rations.

Reciprocal Insurance Benefits

Sir WILLIAM DARLING asked the Minister of National Insurance what countries had accepted reciprocal insurance arrangements with the United Kingdom and if she was taking further steps to widen the area of such arrangements—Dr EDITH SUMMERSKILL replied "Reciprocal arrangements are in operation with Northern Ireland and the Isle of Man for National Insurance, Industrial Injuries Insurance, and Family Allowances with the Irish Republic for Sickness, Maternity, and Unemployment Benefits, and for the insurance of seamen with New Zealand for Family Allowances and with France for National Insurance and Industrial Injuries Insurance. A multilateral agreement on social security signed by the five Brussels Treaty Powers has been ratified by this country. Negotiations are taking place for further agreements with Australia, the Irish Republic, France, Belgium, the Netherlands, Luxembourg, Denmark, Italy, and Switzerland. Negotiations with the Federal Republic of Germany are due to begin next month. The possibility of making bilateral and multilateral agreements on social security similar to those made by the Brussels Treaty Powers is being examined by a Committee of Experts set up by the Council of Europe."

Industrial Pneumoconiosis

In answer to a question Dr SUMMERSKILL said that since July 25 she had extended insurance under the Industrial Injuries Act against pneumoconiosis to persons using power driven tools to free metal castings from adherent siliceous substances. She was fully aware that pneumoconiosis required very careful investigation and therefore she was referring the whole matter to the Industrial Injuries Advisory Council.

Public Health

Poliomyelitis

In England and Wales notifications of poliomyelitis during the week ended Nov 11 were: paralytic 161 (147), non-paralytic 64 (57), total 225 (204). The figures for the previous week, compared with which there was an increase of 21 notifications, are in parentheses. Notifications for the corresponding weeks in 1947 and 1949 totalled 210 and 316.

Total uncorrected notifications for 1950 up to and including the week under review are 7972. The corresponding figures for 1947, 1948, and 1949 are 8475, 2113, and 5905.

Significant increases compared with the preceding week occurred in Cheshire (10), Dorset (10), and Durham (8). The most significant decreases were in Warwick (5) and Denbigh (5).

It is unlikely that this check in the recent steady decline of notifications is more than transitory.

In England Now

A Running Commentary by Peripatetic Correspondents

THE brief suspension of the *Radio Times* reminded me of an experience in England Then which I have always wanted to record. "Then" was the first week of the late war. I had left my family on holiday and come home a day or so before war was declared to look after the house, which then, odd as it now seems, lodged two maids. I found (to quote E. M. Forster) "panic and emptiness," no practice, no work of any kind except a little laying of sandbags to make street shelters, not even war—only rumours. Time passed slowly.

I don't want to libel the B.B.C., but unless memory plays me very false everything on their printed menu was scratched and the listening ear and hungry soul were fed exclusively on news, inevitably bad, on boasts of the incredible number of beds provided for tomorrow's civilian gassed and wounded, on calls to action strongly tinged with "take cover" and "safety first," and on something that for want of a more descriptive name must be called music.

I felt compelled to listen, in case some real news came through, and because I had nothing else to do, but it brought me very low. There was no real war, nothing dropped from the skies, and yet, it seemed, every flower of our civilisation was as dead as dahlias after the first frost, and weeds were rushing in to fill the gaps. Once before "the lights had gone out all over Europe," but then at least there had been darkness and the flash of guns, this time it was as though every decent light went out at one puff or switch off and in their place shone neon signs advertising chewing gum. Up to now, wars had been heralded by drums and trumpets, ours came in to the wailing of saxophones and the moans of the crooner. Trumpets, if there were any, had mutes in their mouths.

I had suffered before from cardiopneumonia but this was a notable attack. The heart may not have reached the boots but it sagged deep into the pelvic cavity and there it stayed for an eternity of days—perhaps seven—and then the thing happened. It happened, I think, at some unlikely time of day and unannounced—probably it followed official instructions about "evacuation." There was the sound of an orchestra tuning up, a pause, and then—as it were a skylark singing in November—the Overture to the Magic Flute.

The heart, beating wildly, rose from the pelvis to the upper thorax, traversing the diaphragm, which for some time went into fibrillation. Presently both heart and diaphragm settled down, and that is the end of the story, but who, I still want to know, was the unnamed national hero who assembled and conducted that orchestra and chose that work to play? Who were the players—angels from Heaven? How many, besides myself, walking in darkness, suddenly at that moment saw a great light? How many, eleven years later, dare not tell that simple story by word of mouth because they would again be seized by fibrillation of the diaphragm?

* * *

Years ago, the hospital outpatient who didn't know the ropes was lucky to be seen by the consultant within four hours, and many spent the day on the job, but I had hoped things were different in these halcyon days. Apparently I was wrong.

Three weeks after a small orthopaedic operation my wife received a card summoning her to Mr. X's 10 A.M. outpatient session at a teaching hospital in the provinces. After a twisty 15-mile car journey, she duly reported to the orthopaedic subsection 5 minutes before time. Queues stretched in all directions. With the simple faith of the novice she asked a porter where Mr. X held his clinic. "Let me see your card," he replied. "Why, you should be in the general outpatients along there." She hobbled a painful quarter mile in the direction indicated to further queues. No hoarding enlightened her search, so she inquired for Mr. X's clinic from another porter. "Never eard of im," he retorted, "but since 'e's orfapædic it'll be in the orfapædic outpatients quarter mile along there." "But I've just come from there," she

their appointment and found that Dr J D Paulett was granted by the LCC a house compulsorily acquired from a private owner. Having got those premises he applied to the Medical Practices Committee saying that he had been granted the doctor's house on the estate and asked for permission to practise. At that time other doctors had submitted their names to the LCC as wishing to practise, but only the name of Dr Paulett appeared to have gone forward, and as there was only one applicant in the field the Medical Practices Committee had no option but to appoint him. One of the three other doctors who were later appointed also applied to the committee for permission to practise, saying he had premises and facilities given him by the LCC. Miss Hornsby-Smith urged that the position of the MPO was prejudiced when they had only one name submitted to them and when that applicant claimed that he had the premises and that virtually he was allowed to start up in practice. The LCC by deciding which doctors should be allocated a house from which to practise were in fact choosing the doctors on this estate and usurping the statutory right of choice of the MPO. She asked that applications by doctors wishing to practise in these areas should be submitted to the MPO who could then say to the local authority "we choose doctors A, B, and C, and we look to you to provide accommodation for them." Mr PERCY DAVIES: Is the hon Lady saying that these doctors were chosen because they were Communists? Miss HORNSBY SMITH replied that she thought the selection of names to go forward to the Medical Practices Committee showed signs of definite political prejudice.

Mr ARTHUR BLENKINSOP bitterly resented the manner in which the subject had been raised, especially the implicit suggestion that the political views of doctors should be taken into account on their appointment. The whole medical profession desired to have freedom for doctors to set up practice. On the broader issue raised, he continued, any doctor might apply to practise in an area, and could only be refused if the area was overdoctored. Vacancies were advertised only when a sitting doctor withdrew or where the area was underdoctored.

Dr CHARLES HILL thought this was an instance of a general difficulty underlying the machinery of the Medical Practices Committee. If a vacancy arose through the death or retirement of a doctor and it was decided to fill the vacancy, and the full procedure of advertisement and selection had been followed, then if a doctor—whether he was an applicant or not—had obtained by purchase or otherwise premises from which the practice was conducted, or the only appropriate professional premises in the area, it was difficult to make an effective choice of any other person. That was the difficulty which the Medical Practices Committee, with the co-operation of the medical profession, were trying to tackle. Whatever other issues might be involved in this case, there was, he urged, a general problem. It would be a pity, he thought, if the new National Health Service machinery were short-circuited by a local authority who named a doctor as tenant. He thought there was good reason for the LCC to follow another method to ask the official machinery to advertise the vacancy and to allot the house to the selected doctor. One general method should be adopted, approved by the Ministry of Health and under the supervision of the MPO, to avoid this instance of tenancy being the best part of the law.

Mr BLENKINSOP said he appreciated the points which Dr Hill had raised and the Ministry would be prepared to look into the question. What he resented so deeply was the implication that this was tied up with some preferential treatment for alleged Communists. There was certainly a problem in relation to doctors' premises, and he could give an assurance that the point would be considered in relation to the discussions which the Ministry were already having with the British Medical Association.

Forster) "panic and emptiness," no practice, no work of any kind except a little laying of sandbags to make street shelters, not even war—only rumours. Time passed slowly.

I don't want to libel the B.B.C., but unless memory plays me very false everything on their printed menu was scratched and the listening ear and hungry soul were fed exclusively on news, inevitably bad, on boasts of the incredible number of beds provided for tomorrow's civilian gassed and wounded, on calls to action strongly tinged with "take cover" and "safety first," and on something that for want of a more descriptive name must be called music.

I felt compelled to listen, in case some real news came through, and because I had nothing else to do, but it brought me very low. There was no real war, nothing dropped from the skies, and yet, it seemed, every flower of our civilisation was as dead as dahlias after the first frost, and weeds were rushing in to fill the gaps. Once before "the lights had gone out all over Europe," but then at least there had been darkness and the flash of guns, this time it was as though every decent light went out at one puff or switch off and in their place shone neon signs advertising chewing gum. Up to now, wars had been heralded by drums and trumpets, ours came in to the wailing of saxophones and the moans of the crooner. Trumpets, if there were any, had mutes in their mouths.

I had suffered before from cardiopneumonia but this was a notable attack. The heart may not have reached the boots but it sagged deep into the pelvic cavity and there it stayed for an eternity of days—perhaps seven—and then the thing happened. It happened, I think, at some unlikely time of day and unannounced—probably it followed official instructions about "evacuation." There was the sound of an orchestra tuning up, a pause, and then—as it were a skirl singing in November—the Overture to the Magic Flute.

The heart, beating wildly, rose from the pelvis to the upper thorax, traversing the diaphragm, which for some time went into fibrillation. Presently both heart and diaphragm settled down and that is the end of the story, but who, I still want to know, was the unnamed national hero who assembled and conducted that orchestra and chose that work to play? Who were the players—angels from Heaven? How many, besides myself, walking in darkness, suddenly at that moment saw a great light? How many, eleven years later, dare not tell that simple story by word of mouth because they would again be seized by fibrillation of the diaphragm?

* * *

Years ago, the hospital outpatient who didn't know the ropes was lucky to be seen by the consultant within four hours, and many spent the day on the job, but I had hoped things were different in these halcyon days. Apparently I was wrong.

Three weeks after a small orthopaedic operation my wife received a card summoning her to Mr. X's 10 A.M. outpatient session at a teaching hospital in the provinces. After a twisty 15 mile car journey, she duly reported to the orthopaedic subsection 5 minutes before time. Queues stretched in all directions. With the simple faith of the novice she asked a porter where Mr. X held his clinic.

"Let me see your card," he replied. "Why, you should be in the general outpatients along there." She hobbled a painful quarter mile in the direction indicated to further queues. No hoarding enlightened her search, so she inquired for Mr. X's clinic from another porter. "Never 'eard of 'im," he retorted, "but since 'e's orfapaded it'll be in the orfapaded outpatients quarter mile along there." "But I've just come from there," she

remonstrated "Well, then," he said, "they've told you wrong, me dear—see." Now completely bewildered, she asked a passing lady doctor, who thought Casualty Sister would know, and Casualty Sister said she'd ring the chief outpatient secretary and find out. An hour after the appointed time the reply came "Mr. N's clinic is where you first reported." So back she went, got a card from one secretary, took it to a second secretary, and was given an appointment for another day. On producing her original summons she was reprimanded and told to sit at the bottom of the queue. Hours dragged by. At 12.45 she was at last ushered into the holy-oh-holes—and seen by the house surgeon.

She was late home, and I needed the car to drive 25 miles to my afternoon clinic. So my poor patients had a distressful wait. The bitterest pill came two days later, when I bustled into my other hospital to find that the outpatient department had been remodelled and restaffed while I was on holiday. "Where are Surgical Outpatients being held," I asked a pert young piece behind the office window. "Take your place at the bottom of the queue and you'll find out," she said. I will not record my reply.

* * *

"Please come quickly, Doctor. Grandfather has died of the soup."

I had just returned from a holiday, where I whiled away many a stormy afternoon following Detective-Inspector Alleyne or Mr. Albert Campion in their relentless pursuit of homicides, so even as I grabbed my bag and accompanied the agitated young lady across the road to her house I had the whole story clearly in my mind.

He Died of the Soup made a good title. I should be told that after taking his first mouthful of soup the old man leapt to his feet, gasping "I've been poisoned," and then crashed to the floor, his rubicund complexion turning a dusky blue. I should detect a faint odour of bitter almonds. There would be four suspects: the unmarried daughter, whose proposed marriage had been banned by her father only yesterday in a stormy scene; the married daughter with whom the father had lived and whose life he had made a misery; her husband, who needed the old man's money to pay his debts and start a business; and finally the attractive young granddaughter, apple of the old man's eye, who was leading me over, and who by all the rules of detective fiction must have done it. I stole a glance at her with my steely grey eyes (I had decided to be an Alleyne, though my habitual vacant expression would better suit a Campion). She was registering horror and grief so well that for a moment I thought they were real, then I remembered the theatre club photograph I would find on the dining-room piano, with her in the centre as Cleopatra, and her secret histrionic skill was revealed.

Less than two minutes had passed since the tragedy when I was ushered into the dining room, determined to miss no clue. But a single glance at the body shattered my reconstruction of the crime. For the old man had evidently pitched forward on to the table, taking his own plate of soup in the waistcoat and his son's on the forehead. Now he lay crumpled in his chair, the streaks of pea soup down his face clashing hideously with his purple lips and naive cheeks. On auscultation no heart beat disturbed the stillness.

A horde of small grandchildren hung round the door, their eyes bright with the prospect of missing afternoon school. "Do something, Doctor," their mother begged tearfully, while her husband clumsily patted her shoulder. It was the work of a moment for me to fill a syringe with Coramine and plunge the needle between the old man's ribs. Five seconds later he drew a deep breath and then began to pant steadily. I gazed fascinated. The light died out of the grandchildren's eyes, the daughter's sobs gave place to a less becoming sniffle, and her husband dropped her shoulder and went out to the kitchen. The air was heavy with disapproval of my tampering with the course of nature. In a few minutes the old man opened his eyes, looked long at me, and finally glared at his married daughter. Then he set the seal on my discomfiture. "Who," he asked peevishly, "told you to send for the doctor?"

Letters to the Editor

PHYSICAL AND BIOLOGICAL EFFECTS OF ATOMIC EXPLOSIONS

SIR,—Medical readers of your correspondent's very able article on this subject will probably agree with the author's last sentence. They will "find it difficult to remain optimistic." If in addition to the effects of atomic explosions they consider the hazards from biological and chemical warfare, and all these added to saturation bombing with high explosive and incendiaries as well as guided and rocket missiles, optimism will indeed seem misplaced. But why be either optimist or pessimist? Why not realist?

Your correspondent gives an excellent précis of the American book on the subject, with a few interpolations of his own to which he is of course entitled.

Nearly all the information in the book, and a good deal besides, has been in the hands of those working at Civil Defence measures for a considerable time, and since I have had more opportunity than many to become conversant with the extensive research, surveying, and general study going on in a dozen centres in this country, and many more elsewhere, I think it important to insist that, however bad a business total war would be, a resolute trained and informed public (the nation at war), with all the aids that would be forthcoming, would find that they had it in their power to face any attack. The losses might be frightful but need not be overwhelming. We have the resolute public. We must have the informed and trained public.

E. ROCK CARLING

* * * As a basis for the realism Sir Ernest demands, we are publishing articles on the medical implications of new methods of warfare. We do so because the risk of war, in this country as elsewhere, can no longer be ignored by the profession, which must prepare itself for what it may have to do. To some of us the Civil Defence training of 1938-39 seemed largely futile—what could the citizen hope to achieve, against air attack, with a bucket and shovel? But the authorities were right then, and they are right now, in bidding us learn to do what we can. This will always be more than we suppose possible.—ED. L.

REVOLT AT KINGSTON

SIR,—Your article of Nov. 11 raises four distinct issues on all of which your conclusions, which showed a considerable hesitancy as if you knew the whole story had not been told, were far from correct.

1. The first issue is that of the regional hospital board's failure to consult or consider local feeling and its refusal to give information as to its plans and the reason for them. The issue raised is how does a board give the public that information if the whole press, lay and professional, refuses to publish it? Local papers, with the exception of the *Richmond & Twickenham Times*, have given entirely one-sided and inaccurate versions of the proposals. Nationally, news has to be "exciting", so the "revolt of 26 doctors" becomes more important and space worthy than the plans of the R.H.B. to provide the best possible service for 225,000 people having only some 1100 beds with which to do it.

On Nov. 5 one newspaper used more than a column of its scanty space to a statement of the case against the R.H.B. On Nov. 10 the hospital management committee heard a statement by its chairman which in six foolscap pages, handed to the press, set out the board's policy as he saw it. On Nov. 12 the same newspaper published 14 lines on the subject without one word of that statement.

How can we then tell the public the facts if this is how the press treats them? The press has been present at every meeting of both R.H.B. and H.M.C. at which this

question has been discussed, and all reports on it have been made available to them

2 The second issue is who is to decide on the best use of hospital beds and how is the decision to be reached? If the amount of consideration given to the Kingston Victoria's case is not enough, what more must be done? Here, briefly, is its history. In 1938 the Surrey Committee of the Nuffield Provincial Hospitals Trust discussed the future of the hospital and asked local views on the question. In 1941 the two Kingston hospitals were used as an outstanding example of how *not* to organise a hospital service in discussions on the B.M.A.'s Medical Planning Commission, which declared that "from the two separate hospital systems there should be evolved one co-ordinated system, unified centrally and locally." In 1942 a committee met in Kingston to discuss this and other health problems and the Victoria Hospital was represented at these meetings. In 1948 the G.P.s who had previously exercised a close control on the number of doctors using the Victoria, began to add both G.P.s and specialists to the staff in order to forestall changes under the N.H.S.

Then came the medical review of the region, when a subcommittee of the board's medical advisory committee visited the Victoria and met the whole of the staff. I had the privilege of attending both as a member of the evidence-collecting committee and as one of the Victoria's staff. When asked what was the greatest need of the district the reply was, unanimously, "maternity and gynaecological beds, with orthopaedic a close second." This was confirmed later when the local borough council sent a resolution to the board calling for increased maternity accommodation and when the Kingston medical advisory committee declared that "the provision of an adequate gynaecological unit must be the first consideration."

Those opinions were considered by the medical review committee, by the Surrey area committee, by the maternity subcommittee, and finally by the region's medical advisory committee which decided on the present scheme. It is a gross misrepresentation to talk of the Victoria being closed down. There are 10 male beds to be moved, and that is all the change from the patient's angle. It will cease trying to do medicine, surgery, gynaecology, urology, E.N.T., and eyes in 32 beds with a total medical staff of 34 while the real Kingston Hospital (older and doing 80% of the work of the district) is also doing all these jobs across the street. As the Hospital Survey (Gray and Topping) showed this area has less than half the beds it needs and must use them to the maximum.

3 But what about G.P. beds? The South-West Metropolitan Regional Hospital Board and its medical advisory committee are on record unanimously as in favour of providing such beds as it can for G.P.s in the terms of Circular 132 of the Ministry for such things as are within the competence of the family doctor. The average bed occupancy of the Victoria last year was 33 and the board has offered 38 in exchange. It has offered money to make such changes as the G.P.s want, and it expected co-operation in a trial of how G.P.s can staff and run a hospital inside a hospital service mainly based on specialists.

But we must not exaggerate this question. In the country as a whole not more than 10% of G.P.s have hospital beds and not more than 5% of the total of hospital care is given by G.P.s. Kingston Victoria Hospital was in transition with G.P.s playing a smaller and smaller role as the years went on. At neighbouring Richmond the G.P.s have themselves changed their hospital to a specialist unit without any public outcry at any time. In this hospital group there are 121 G.P.s. There are no beds solely under G.P.s. All the smaller hospitals have regular specialist cover. The regional

board's offer to equip the Surbiton Annexe for the G.P.s to be run and controlled by themselves—as many of them are cared to accept the invitation—should have been welcomed as a first attempt to deal with "one of the potential weak spots in the service."

Let me add that the staff at Kingston Hospital are in the closest touch with the G.P.s of the area and that there is an open access laboratory available, and that X-rays can be obtained either by direct access at the Victoria or through the physicians at the Kingston Hospital—the choice being left to the G.P.s.

When the present changes at Kingston are complete it can be an excellent hospital group, with a G.P. hospital, 600 beds for acute medicine and surgery, 200 beds for chronic, sick, a 130 bed maternity unit and gynaecological unit, 60 children's beds, 48 for tuberculosis, 36 for orthopaedics, and 30 for infectious diseases, with the long established eye unit of 12 beds at Richmond.

4 Then why revolt and what is to be our attitude in the matter? Let me remind you that the staff at Kingston Victoria have never held a meeting to discuss this question. It is not accidental that those members of the staff able to put the matter in perspective have been excluded from any discussions that have taken place. The scheme has the support of the 80% of the population who use Kingston Hospital for all their major ailments. The same doctors who make so much disturbance about the Victoria send the bulk of their cases into Kingston Hospital. It must clearly be recognised that the small number of patients using the Victoria are the privileged section of the G.P.s' practice and that they are not unconnected with whatever private practice continues to exist or with the fact that 10 of its 32 adult beds have hitherto been Section 5 beds. The National Health Service and its agencies have to provide a service for the whole population not for privileged groups.

Wiser counsels must prevail. No patient will suffer medically by the proposed changes, but the longer the foolish revolt against the health service goes on the lower becomes the standing of the family doctor in the eyes of the sick. To ally oneself with one political party and use high pressure publicity methods in a matter which is beyond the political stage, and at the same time to refuse to sit round a table with those who have the arduous task of running the hospitals, is to bring the medical profession into disrepute.

Kingston Group Laboratory

D STARK MURRAY

INTERNATIONAL SOCIETY OF HEMATOLOGY

SIR,—In your account (Sept 23) of the Cambridge congress of the International Society of Hematology in some places my real meaning has been lost. Since several of my colleagues have been quick to charge me with a complete change-about from my usual opinions, I make haste to try to make them clear.

In describing the session on "Hypersplenism," in which there were several papers dealing with splenectomy in leukaemia and related states, your report says that I "had seen no good results in eighteen splenectomies done for leukaemia." This is certainly not the case, since I have seen brilliant results occasionally. What I did say was that our own results did not warrant undue optimism for the relief of the anaemia by splenectomy in most cases of leukaemia. I thought that some degree of caution was necessary against the indiscriminate use of this operation in leukaemia. The unkindest cut however, was a statement that the discussion had confirmed my growing opinion "that hypersplenism was a romantic subject devoid of scientific truth." In view of my known propensity to espouse the cause of hypersplenism vigorously and to try on every occasion possible to adduce evidence in favour of it, this statement hardly seems credible. I hasten to point out, therefore, that

remonstrated "Well, then," he said, "they've told you wrong, me dear—see" Now completely bewildered, she asked a passing lady doctor, who thought Casualty Sister would know, and Casualty Sister said she'd ring the chief outpatient secretary and find out. An hour after the appointed time the reply came "Mr X's clinic is where you first reported." So back she went, got a card from one secretary, took it to a second secretary, and was given an appointment for another day. On producing her original summons she was reprimanded and told to sit at the bottom of the queue. Hours dragged by. At 12.45 she was at last ushered into the holy-olives—and seen by the house surgeon.

She was late home, and I needed the car to drive 25 miles to my afternoon clinic. So my poor patients had a distressful wait. The bitterest pill came two days later, when I bustled into my other hospital to find that the outpatient department had been remodelled and restaffed while I was on holiday. "Where are Surgical Outpatients being held," I asked a pert young piece behind the office window. "Take your place at the bottom of the queue and you'll find out," she said. I will not record my reply.

How can we then tell the public the facts if this is how the press treats them? The press has been present at every meeting of both R.H.B. and H.M.C. at which this

REGISTRARS

SIR,—The threatened cut in hospital registrar establishment seems to me inevitable, but I disagree seriously with its suddenness. A reduction of 50% in this group immediately—or possibly spread in a limited way over two years by retention in temporary gradings—is bound to cause serious unemployment and dissatisfaction. Unless this change is accompanied by a good deal of reorganisation, which it would seem impossible to institute overnight, the efficiency of many hospitals must be impaired. There is much truth in the suggestion that registrars do the work of hospitals.

The situation at my own hospital will serve as an illustration. The present staff for 450 acute and 300 chronic patients (the latter, I believe, seriously underdoctored and undernursed) is

	Specialists	Registrars	House-officers
Full time	8	11	10
Part-time (as units)	1½, approx	½, approx	all

The cut can be expected to reduce our registrars to 6 (possibly 4 registrars and 2 senior registrars). For it seems to be a maxim of the hospital service to scale things up or down according to previous local standards and never according to national standards. The percentage change seems to be the only thing standardised. How shall we manage two large medical teams, two surgical teams, 30 gynaecology and 80 midwifery beds (expanding numbers), and anaesthetics—apart altogether from smaller departments—with these 6? Here are some possible ways.

1 *Work the specialists harder?* This means the full time staff, because, as is well known, part-time people are seldom at hand for emergencies. One colleague lives 20 miles away, and the average distance for all of us is 8½ miles. The hospital does an enormous amount of emergency work, and if a team had no registrar resident on duty, surgeons, physicians and midwives would have to live in or risk being fetched back probably 10–15 times per month. This at present happens on the surgical firms when the registrar is on holiday.

The non urgent work freed by the absent registrar would also be enough to make great inroads on the consultants time and this would be a permanent obstruction to their routine work, and would seriously interfere with necessary consideration, discussion, reference, and so on.

2 *Work the remaining registrars harder?* With rare exceptions this is impossible.

3 *Work housemen harder?* This is possible in some cases. The big trouble is the question of responsibility by a rather "green" officer, especially at night.

4 *Appoint more specialists?* Here is a partial answer, but there seems to be no immediate prospect of increasing the specialist establishment. As an example of the official frame of mind, senior regrading has been delayed till 1951. In any case we need resident responsibility, and there is no general arrangement or accommodation for this. My own department (anaesthetics) is already top heavy—we have 1½ non resident specialists and a full time resident registrar.

5 *Appoint more housemen?* Again a partial answer. First there is the difficulty about responsibility, already mentioned. Secondly there is a shortage of applicants, and this is sure to become more acute for a time in special departments when the registrar bottleneck is narrowed. Housemen want supervision which shortage of staff prevents. Experience which we can offer freely, a "handle" to a reference which we cannot often give, and pleasant surroundings, which we have not. Even now we cannot always fill vacant posts. The Ministerial alternative of employing part time general practitioners will certainly not work in most town areas. Again, we need locally resident people for emergencies. Many of our GPs live away from the district.

I do not think one can argue seriously against the reduction of registrar complements, but the change ought to be a gradual one and accompanied by changes in organisation and staffing so that the work they now do will continue to be done.

SIR,—It was reasonable to assume that behind the creation of large numbers of registrar posts during the last two years there was some general plan. If the health service accepted a man for training, having in mind the Spens report, it was natural to suppose that, with a planned scheme, there would be a fair chance of his obtaining an appointment for which he had been trained. It now appears that the Ministry of Health has at last realised, too late, that there are more registrars than can possibly hope for consultant posts with present establishments. (These establishments are, on Lord Moran's authority, only 56% of the optimum size¹) What is probably more to the point, expenditure has to be cut, and what more convenient way than to cut where politically the hurt is least and where those affected are, with assistants in general practice, the most vulnerable members of the profession?

A registrar, like most others, now has a poor chance of obtaining any employment in general practice—let alone congenial employment—with general practice constituted as it is in many areas at present.

For the hospital service one risk of the cuts is that registrars will be concentrated in the teaching hospitals. No student can learn medicine properly without attending a hospital which serves fully a definite community, taking all comers who need attention, and associating itself with the general practitioners in the community. In London many non teaching hospitals are beginning to satisfy these criteria. The Ministry's ruling may put a stop to this progress, which cannot continue without registrars with experience and with enthusiasm. Enthusiasm cannot be got—still less maintained—unless these men have a future to look forward to. It cannot be got by staffing with junior hospital medical officers with no future, or by clinical assistants from general practice even if this were possible.

Many registrars are in the 30s with a wife and family to support and four to six years' war service behind them. For such men there is little attraction in the Armed Services, Middle East, or South East Asia. They have usually had quite enough of all three already. Moreover they, like many others in the Armed Forces and Colonial Service, are wondering what they would do on retirement at a relatively early age with a poor pension and family commitments. It is already extremely difficult for a man of 40 to get into general practice, how much more difficult for a man of 50 or 55! Consultant practice would be out of the question.

The crux of the matter is that the Minister of Health plus some senior members of the profession would rather see the public get their bottles of medicine, wigs, false teeth, glasses and administrators than make the necessary number of consultant appointments. There is now to be direction of labour by the old trick of economic blackmail. We were told that this would never happen again.

Eidov

SIR,—At last the number of trainee specialists is to be reduced to something approaching mathematical equilibrium with the consultant posts available. Few thoughtful registrars can fail to welcome the impending finale of this most unsatisfactory epoch. Were the process of thinning to be as far as possible in the circumstances, and were all hope not removed, hundreds, including myself, though bitterly disappointed, would be prepared, if unlucky, to bow before the axe. But there are portents in your annotation of Nov 11 that the thing may not be done with equity, and I wish to state two points of much importance.

In this annotation you say that a Scottish survey showed there to be many more vacant consultantships

I am still convinced (a) that hypersplenism exists, and (b) that a certain amount of evidence for it is present. Unfortunately, this is almost all in the clinical field and as yet no clear cut experimental evidence has been brought to bear on the problem.

On my contribution to the discussion of "haemolytic anæmias" the report again goes astray. It states that "experience with leukaemia, even when auto-haemolysis were present, was uniformly unfavourable." This is by no means what I said, since I brought to the meeting the report of three cases of leukaemia or lymphosarcoma with symptomatic haemolytic inæmia treated with ACTH and in which the results of treatment were striking. The report goes on to say that "ACTH has been tried, since it is said to influence antibody formation, but the results were equivocal." This statement too is curious, in that the latter part of my paper dealt with the marked effects of ACTH in producing a reduction in abnormal antibody with at the same time dramatic remissions in the haemolytic process. The results were anything but "equivocal."

Further on it is recorded that I considered "ACTH is not itself of practical therapeutic value in leukaemias." This might be a fair statement for the acute cases, but in certain of the chronic varieties, particularly with a haemolytic complication, or in the terminal anæmia or the exfoliative dermatitis of certain cases of chronic lymphocytic leukaemia, the results were at times of considerable value and therefore must be considered to be of practical importance.

Two other small points. The report is headed "International Congress of Haematology," and is called "the third of its kind." Actually it was the second congress of the International Society of Haematology.

While in this critical mood, may I also take exception to a statement in your otherwise excellent leading article entitled *Haematology*? Here you say "much haematology, of course, lacks a really scientific basis, witness the discussions on hypersplenism and haemolytic anæmias." To those of us who have worked busily in these fields, particularly in the latter one, where considerable exact knowledge has been obtained, this statement is, to say the least, a little disconcerting.

DANGER OF HEXAMETHONIUM

SIR,—I wish to reinforce the warning given by Dr Hills and Dr Kelly in your issue of Nov 11. In this department experience with hexamethonium is limited to five cases, but in one of these the reaction was far more severe than any yet described.

The patient was a man, aged 30, with severe hypertension, reaching 230/130 mm Hg, which had, after thorough investigation, been diagnosed as "essential." His hypertension has been known to exist for 8 years, and 7 years ago he developed thrombosis of the central retinal artery. His heart is now considerably dilated, and he had signs of pulmonary congestion.

Test doses of hexamethonium bromide given intramuscularly and intravenously showed that he was unusually insensitive, even 100 mg intravenously on one occasion caused only a slight drop in blood pressure.

Hexamethonium bromide was then given orally over a period of 10 days, the dose being stepped up cautiously from 0.25 g tds to 1.5 g tds on the 10th day. No response of any kind was seen during this period, except slight constipation on the 7th and 9th days. The basal blood pressure remained essentially unchanged at about 180/110 mm Hg. On the morning of the 11th day he collapsed quietly and without warning when sitting in the w.c. He was not discovered for about half an hour, and was then found to be stuporose. His blood pressure was 100/60 mm Hg. The pupils were dilated and fixed, and his speech was slurred. He was incontinent of faeces but bowel sounds were completely absent.

This condition persisted for 24 hours, though his blood pressure rose to 180/100 mm Hg under the influence of adrenaline and ephedrine. After this his blood pressure rose spontaneously to its previous levels. Extensor plantar reflexes developed, the other signs persisted unchanged. The illness recurred intermittently for 9 days, varying in severity from day to day. The cerebral condition is improving, but he is still drowsy and dysarthric after 16 days and has amnesia for the fortnight preceding his collapse.

The precise causation of these complications appears to be (1) sudden excessive blockage of the autonomic ganglia (hypotension, pupillary paralysis, ileus, and incontinence), and (2) cerebral cortical ischaemia (drowsiness, amnesia, dysarthria, and extensor plantar responses).

This case strongly supports Dr Turner's warning in his article of Sept 2 that a new era of treatment has not come, and that the effects of so powerful a drug should always first be assessed in a hospital. It would appear to be very risky to use the drug indiscriminately in hypertension, either in the outpatient department or in general practice, until more is known about the avoidance of such complications.

SITUATION VACANT

SIR,—Now that Bernard Shaw has gone, who will take his place as Hammer of the Doctors? A thorn in the profession's side for more than fifty years, Shaw nevertheless performed a valuable public duty as chief critic, for it will not have escaped the notice of observant onlookers how remarkably uncritical of itself is the medical profession. Every profession needs to be jolted out of its smug complacency at regular intervals, and as it is obvious that, in the case of Medicine, such a shaking up is very unlikely to come from within the profession, then it must come from without—from a layman and, moreover, from a prominent layman. The necessity for this is evident when one considers how seldom any word appears in the popular press in any way critical of the skill and competence of doctors. Such, of course, never appears at all in the medical press, and there appears to be a tradition among news paper and other editors that the subject is taboo, only men like Shaw stood any chance of making their views known at all, because Shaw was news whatever he said.

Why the medical profession should enjoy such immunity is hard to understand, as it is essentially a public service and all public services must be open to critical analysis and review if they are to function efficiently. This is surely a fundamental of democracy, and the fact that the medical profession is so undemocratic in itself should not be allowed to interfere with this process. The lack of such frank comment in the past accounts in some part for the astonishingly poor historical record of the medical profession, a record which shows again and again that doctors, whether organised or not, have consistently obstructed progress throughout the ages, and were rarely in the van of social or medical reform. The persecution suffered by Lister and Simpson among others comes to mind as a notable example, and the opposition in more recent years to the establishment of the Ministry of Health and other progressive measures is in keeping with this tradition.

In short, then, we need some person or persons to keep us on our mettle, to expose deficiencies in medical practice and custom, to shake us out of the stagnant lethargy which will otherwise inevitably be our lot. Shaw, while in many ways falling short of the ideal, was a stimulating man to have around, as was Chadwick, who also scorned the doctors, before him. I suggest that some worthy successor to these two stalwarts be cordially invited to fill the vacant position.

London N 4

ADAIR GIBBY

REGISTRARS

SIR,—The threatened cut in hospital registrar establishment seems to me inevitable, but I disagree seriously with its suddenness. A reduction of 50% in this group immediately—or possibly spread in a limited way over two years by retention in temporary gradings—is bound to cause serious unemployment and dissatisfaction. Unless this change is accompanied by a good deal of reorganisation, which it would seem impossible to institute overnight, the efficiency of many hospitals must be impaired. There is much truth in the suggestion that registrars do the work of hospitals.

The situation at my own hospital will serve as an illustration. The present staff for 450 acute and 300 chronic patients (the latter, I believe, seriously underdoctored and undernursed) is

	Specialists	Registrars	House-officers
Full time	8	11	10
Part time (as units)	1½ approx	½ approx	nil

The cut can be expected to reduce our registrars to 6 (possibly 4 registrars and 2 senior registrars). For it seems to be a maxim of the hospital service to scale things up or down according to previous local standards and never according to national standards: the percentage change seems to be the only thing standardised. How shall we manage two large medical teams, two surgical teams, 30 gynaecology and 80 midwifery beds (expanding numbers), and anaesthetics—apart altogether from smaller departments—with these 6? Here are some possible ways.

1 *Work the specialists harder?* This means the full time staff because, as is well known, part-time people are seldom at hand for emergencies. One colleague lives 20 miles away, and the average distance for all of us is 8½ miles. The hospital does an enormous amount of emergency work, and if a team had no registrar resident on duty surgeons, physicians, and midwives would have to live in or risk being fetched back probably 10–15 times per month. This at present happens on the surgical firms when the registrar is on holiday.

The non urgent work freed by the absent registrar would also be enough to make great inroads on the consultants' time and this would be a permanent obstruction to their routine work, and would seriously interfere with necessary consideration, discussion, reference and so on.

2 *Work the remaining registrars harder?* With rare exceptions this is impossible.

3 *Work housemen harder?* This is possible in some cases. The big trouble is the question of responsibility by a rather green officer especially at night.

4 *Appoint more specialists?* Here is a partial answer but there seems to be no immediate prospect of increasing the specialist establishment. As an example of the official frame of mind S.H.M.O. regrading has been delayed till 1951. In any case we need resident responsibility, and there is no general arrangement or accommodation for this. My own department (anaesthetics) is already top heavy—we have 1½ non resident specialists, and a full time resident registrar.

5 *Appoint more housemen?* Again a partial answer. First there is the difficulty about responsibility, already mentioned. Secondly there is a shortage of applicants and this is sure to become more acute for a time in special departments when the registrar bottleneck is narrowed. Housemen want supervision which shortage of staff prevents experience which we can offer freely a handle to a reference which we cannot often give, and pleasant surroundings which we have not. Even now we cannot always fill vacant posts. The Ministerial alternative of employing part time general practitioners will certainly not work in most town areas. Again, we need locally resident people for emergencies: many of our G.P.s live away from the district.

I do not think one can argue seriously against the reduction of registrar complements but the change ought to be a gradual one and accompanied by changes in organisation and staffing so that the work they now do will continue to be done.

London E 11

E J W BARNARD

SIR,—It was reasonable to assume that behind the creation of large numbers of registrar posts during the last two years there was some general plan. If the health service accepted a man for training, having in mind the Spens report, it was natural to suppose that, with a planned scheme, there would be a fair chance of his obtaining an appointment for which he had been trained. It now appears that the Ministry of Health has at last realised, too late, that there are more registrars than can possibly hope for consultant posts with present establishments. (These establishments are, on Lord Moran's authority, only 56% of the optimum size.) What is probably more to the point, expenditure has to be cut, and what more convenient way than to cut where politically the hurt is least and where those affected are, with assistants in general practice, the most vulnerable members of the profession?

A registrar, like most others, now has a poor chance of obtaining any employment in general practice—let alone congenial employment—with general practice constituted as it is in many areas at present.

For the hospital service one risk of the cuts is that registrars will be concentrated in the teaching hospitals. No student can learn medicine properly without attending a hospital which serves fully a definite community, taking all comers who need attention, and associating itself with the general practitioners in the community. In London many non teaching hospitals are beginning to satisfy these criteria. The Ministry's ruling may put a stop to this progress, which cannot continue without registrars with experience and with enthusiasm. Enthusiasm cannot be got—still less maintained—unless these men have a future to look forward to. It cannot be got by staffing with junior hospital medical officers with no future, or by clinical assistants from general practice even if this were possible.

Many registrars are in the 30s with a wife and family to support and four to six years' war service behind them. For such men there is little attraction in the Armed Services, Middle East, or South East Asia. They have usually had quite enough of all three already. Moreover they, like many others in the Armed Forces and Colonial Service, are wondering what they would do on retirement at a relatively early age with a poor pension and family commitments. It is already extremely difficult for a man of 40 to get into general practice, how much more difficult for a man of 50 or 55! Consultant practice would be out of the question.

The crux of the matter is that the Minister of Health plus some senior members of the profession would rather see the public get their bottles of medicine, wigs, false teeth, glasses and administrators than make the necessary number of consultant appointments. There is now to be direction of labour by the old trick of economic blackmail. We were told that this would never happen again.

Edgar

SIR,—At last the number of trainee specialists is to be reduced to something approaching mathematical equilibrium with the consultant posts available. Few thoughtful registrars can fail to welcome the impending finale of this most unsatisfactory epoch. Were the process of thinning to be as far as possible in the circumstances and were all hope not removed hundreds, including myself, though bitterly disappointed, would be prepared, if unlucky, to bow before the axe. But there are portents in your annotation of Nov 11 that the thing may not be done with equity, and I wish to state two points of much importance.

In this annotation you say that a Scottish survey showed there to be many more vacant consultantships

in branches such as radiodiagnosis, psychiatry, and tuberculosis than in general or orthopaedic surgery. The Ministry, in its announcement published in the same issue, states that senior registrars should be appointed for a fourth year but rarely, and then mainly in such branches as neurosurgery and thoracic and plastic surgery. Referring to the Scottish survey you state "These difficulties will no doubt be acknowledged in settling the distribution of registrarships within the new total establishment."

Perhaps I misapprehend, Sir, but that could mean that you favour giving a larger number of senior registrarships, pro rata, to these narrower specialties than to the basic crafts of, say, general medicine and surgery. With all deference to my friends in such branches, has not this tendency gone far enough? We already have a position in which, in all save pay, the status of the senior surgeon of a hospital is no more than equivalent to that of a junior member of a non clinical specialty who happens to have been awarded consultant rank. Must expediency drive the authorities to give the plum registrarships to admittedly important, but smaller and less popular, specialties—to the detriment of the traditional status and wide sphere of usefulness of the general physician and surgeon?

My second point is of even more fundamental importance. We are told

(a) As soon as possible the number of registrars is to be drastically reduced. Where necessary, they are to be replaced by part time clinical assistants recruited from general practitioners "normally with higher qualifications and experience as senior registrar or registrar." Fair enough.

(b) At the end of his term of appointment the unfortunate registrar or senior registrar is to be ruthlessly dismissed, to make way for another—younger, cheaper, and equally expendable.

Cannot the Ministry see that this in no way solves the registrar problem? More and more trainee specialists will go through the mill and topple over into general practice. At the all-too rare interviews for consultant ship the same old faces will be seen, many now in general practice and holding clinical assistantships in their specialty. Constantly new faces will be appearing. The once keen and proficient young man will, about the age of forty, cease to be short listed and will become a disgruntled and therefore probably inefficient G.P. And one can see no relief from this position.

No, Sir. The answer is simple. Subject to the individual hospitals' discretion, the periods of tenure of the surviving registrarships should be lengthened, on a year to year basis, instead of being rigidly curtailed. We cannot all be consultants. It is fairest that the major disappointment should be shared among the younger doctors who are not yet deeply rooted in their specialty. The most brilliant and tenacious among them could still make the grade. But the pressure from below would slacken, and gradually a fair and reasonable proportion of the present generation of registrars would be absorbed into the ranks of the consultants.

E. G. HARDY

First Assistant, Department of Surgery
Norfolk and Norwich Hospital

SIR,—Your leading article last week is entirely inadequate as an analysis of the situation created by the cynical document from Whitehall which has been mis-called by its authors a memorandum on appointments to registrar grades.

This so-called memorandum is not related to reality, and carries a degree of cynicism in paragraph 12 which is an insult to the profession. The only proper action for the profession is to repudiate this irresponsible document, to remind the Minister that such lapses from moral sensibility will be treated with the contempt they

deserve, and to place before the regional hospital boards a strong statement to this effect, coupled with constructive proposals for dealing with the situation. This course of action was unanimously endorsed at a recent meeting of the consultants and senior administrative personnel of the Archway group hospitals (whose membership comprises the staff of the Whittington Hospital, New End Hospital, and others), and we write to ask that you assist in making this energetic response to the Ministry's administrative lapse as widely known as possible.

Integrity and decency are still very much alive in our profession, and the only course that can be adopted by a profession conscious of its values and its dignity is to repudiate this offensive memorandum in its entirety, whilst signifying our desire to render to the regional hospital boards all possible assistance in solving an administrative problem which undoubtedly exists, which is not new, will take one or two years to solve, and requires thoughtful and considered action by the whole profession. It is not to be solved by the issue of dictatorial and ill briefed circulars from Whitehall.

T. ST. M. NORRIS
H. E. S. PEARSON
J. M. ALSTON
A. F. MOHUN
CECIL D. COYLE

Whittington Hospital
London N 19

SIR,—I have just compared your editorials of the past two weeks with your footnote to a letter of mine published on April 2, 1949, in which you say "Many more specialists are needed and it would therefore be a misfortune if financial cuts reduced the number of trainees."

I should like to make the following observations.

1. For years past even the best-informed authorities, you included, have been encouraging us to pursue our training as registrars, in anticipation of additional openings under a developing State service.

2. This has led to a situation where there are numerous men who have held higher qualifications for many years, and who have been carrying out responsible work without supervision. This experience will now be utterly wasted, for it is evident that, with the limitation of the number of consultant appointments, the surplus of senior registrars cannot be absorbed by the posts hinted at outside the State service.

3. If these men are to be sacked during the coming summer, does the Ministry and its medical advisors expect them to make a fresh start as assistants in general practice, in competition with their newly qualified pupils—but, alas, without the latter's recent training in midwifery, dermatology, and psychiatry? Ten years' specialisation does not make a good recruit for general practice. In any case, has the attitude of the local executive councils as to vacancies in general practice or of the principals as to assistantships, been fully explored? Here let me briefly inform you of what the chairman of a local executive council in the North East of Scotland said at a meeting of that body. This statement was published last week in the *Aberdeen Press and Journal* in question and answer form.

"Question. Was experience in general practice a good thing in these applications [for a large rural practice]?"

Answer. We had an enormous number of applications from doctors who work in hospitals—well qualified men of the registrar class. But the committee considered that type of candidate was not the type who should get a practice of this size. It was too big a plum."

As to principals, will they accept a man of, say, 38 with an F.R.C.S.? The two I know, when asked, said candidly that they would not dream of it.

4. What machinery is envisaged for senior registrars to find their way back to hospitals as "general practitioner part-time clinical assistants" (G.P.T.C.A.), and what would be their precise function?

5. The Ministry statement establishes that the training period for consultants should be five years. This, compared with the years of devoted and under paid apprenticeship

that many of us older men and women have served, seems a little inadequate

Finally, may I say that the problem has been treated without the least regard for the human beings involved? Surely this type of statistical approach, without an appreciation of individual capacities and qualities, can only lead to unhappiness and discontent

SENIOR REGISTRAR

*** Our correspondent's earlier letter was written shortly before the reviewing committees were due to complete their studies of hospital medical establishments, and the footnote to which he alludes was amplified in a leading article (May 14, 1949) in which we asked whether it was sensible "to allow these trainees, on whom the nation's money has been spent, to scatter a few short months before the hospitals' new complement of staff is made known" In both this article and a later one (Nov 19, 1949) we drew attention to the disproportion between existing establishments of registrars and of consultants and pointed out the registrars' need for immediate information We still believe that "many more specialists are needed", but the health service is now operated within a limited total budget, and we believe that other claims may be even more pressing This aspect is discussed in a leading article on another page.—ED L

SIR,—Of the many remarkable circulars issued by the Ministry of Health since the appointed day, R H B (50) 106 on registrar appointments, summarised in your issue of Nov 11, must rank as one of the most remarkable It might have been thought that in planning an establishment, the volume of work to be accomplished and the needs of patients were factors to be taken into account, apparently, however, these factors must be given low priority The army must not be allowed to expand, for otherwise there will be too many privates without prospect of attaining high rank The winning of wars is a minor consideration!

Croydon.

T W PRESTON

SIR,—The decision of the Minister of Health drastically to reduce the establishment of registrars, and particularly senior registrars, can only be termed short sighted and retrograde Apart from the short term result that more consultants must be appointed or the service to the patient suffer, this policy will lead to a serious reduction in the standards of service in the more distant future

As the new distribution stands, there will be only one registrar trained for each consultant vacancy, and there is no guarantee that the registrar will have been trained in the right specialty when the vacancy occurs Secondly, the new scheme does not allow for a margin of wastage in the ranks of the senior registrars themselves The Ministry circular also points out the need for specialists in the Services, in the Colonies, and in other overseas appointments, but at the same time it cuts out completely the provision of training posts for men who might enter these spheres The net result is that ultimately the average number of applications from senior registrars for consultant appointments will be considerably less than unity

But the most serious result of all will be the elimination of the element of competition for consultant appointments This must progressively lower the standard of our consultant service The antedating of the competitive stage to the selection of senior registrars (and that itself only in part) cannot suffice, as many men emerge from mediocrity during the period of responsibility and experience provided by a senior registrar appointment, while in others weaknesses become apparent In the Services, there must be a large pool of officers of the rank of commander, lieutenant colonel and wing commander from which future officers of flag, field, and air rank may be

recruited The wastage on retirement at commander and equivalent rank is tremendous but is accepted as quite inevitable No one would suggest that the number of lieutenant colonels be restricted to the number of vacancies in the post of colonel or major general! The trained registrars must be kept up in numbers, not only to help with the work of the National Health Service, but in order to provide an adequate pool from which the best may be promoted to consultant rank We cannot have the "pick of the bunch" unless there is a bunch to pick from

The decision was probably made partly as a result of Treasury pressure, but also probably partly as a result of the registrars' own views I do not believe, however, that their hardship and insecurity will be as serious as they have made out, and certainly no worse than that normally faced by registrars and chief assistants in pre war days

May we hope that your influence will be brought to bear to cause a reversal of this new, and I believe retrograde, policy

Canterbury

F G ST CLAIR STRANGE,

SIR,—The question of distinction awards, about which there has lately been much publicity, should be studied in the light of the economies now contemplated in relation to registrar establishments, for the displacement of 1000 registrars with an average income of £1000 per annum will provide the sum allocated for distinction awards

The time has come for our leaders to say whether they are willing to see the younger generation crushed through mis planning, or whether, even at this late hour, the present establishment should be left undisturbed so that the men and women affected can find alternative employment without being subjected to the grave anxiety of finding a post in the short time remaining to them Does not the Hippocratic oath speak of the sharing of livelihoods between pupil and teacher as between father and son? We look forward to a lively correspondence by our elders comparable to that which we have seen from them concerning their distinction awards, so that it may not be said today that the distinction awards of yesterday will be followed by the extinction awards of tomorrow

REGISTRAR.

SIR,—The imminent reduction in the registrar establishment prompts us to make the following observations, for we believe that this action, said to be in the interests of the registrar class, is, in fact, contrary to their wishes

1 *Registrars are prepared for each to be in open competition with his fellows* believing this to be the most certain method of determining the individual best suited for selection to consultant status He is willing to accept the risk that no consultant post may be available for him on completion of his registrar appointments, but believes that the better doctor he can become before entering either general practice or some special branch of the service, the better for the future efficiency of the service

2 *The decision as to who will become consultants will in future be made too soon after qualification*—i.e., before there has been adequate time for all round experience to be gained or assessment of his capabilities to be made

3 *The registrar is at present vital in a service which deals not only with the training of consultants, but also with the treatment of patients* The long term consultant establishment problem may be solved by a 40% reduction in the hospital registrars, but this will be accompanied by a reduction in the efficiency of the service A great deal of the large volume of work at present being done by registrars will, in future, have to be done by senior house officers, who are not qualified to do it If they are sufficiently qualified they should receive the salary of a registrar

in branches such as radiodiagnosis, psychiatry, and tuberculosis than in general or orthopaedic surgery. The Ministry, in its announcement published in the same issue, states that senior registrars should be appointed for a fourth year but rarely, and then mainly in such branches as neurosurgery and thoracic and plastic surgery. Referring to the Scottish survey you state "These difficulties will no doubt be acknowledged in settling the distribution of registrarships within the new total establishment."

Perhaps I misapprehend, Sir, but that could mean that you favour giving a larger number of senior registrarships, pro rata, to these narrower specialties than to the basic crafts of, say, general medicine and surgery. ALEX COMFORT	HAROLD SCARBOROUGH
LANCELOT HOGBen	G BLACK
JULIAN HUXLEY	

THROMBOANGIITIS OBLITERANS TREATED BY HYPOGLYCAEMIA

SIR,—Last year Mazanek¹ reported very favourable results in thromboangitis obliterans treated with hypoglycaemia induced by insulin.

We have applied this treatment in five cases of advanced Buerger's disease, but gave insulin only once a day, with an average of 30–40 administrations in each course. Our patients responded favourably after 1–3 courses, pain disappearing after the first few injections. Circulation of necrotic areas seemed to be accelerated by injections of deoxycortone with vitamin C.

Blood sugar values, which were subnormal in all our cases (58–80 mg per 100 ml.) rose progressively to 116–126 mg per 100 ml. at the end of 30 insulin injections (perhaps through stimulation of glucocorticoid hormone production) and did not return to the initial low values after the 20–30 days' interval between two courses.

Electrocardiograms taken half hourly during hypoglycaemic periods showed flattening and inversion of the T wave, especially in V₄, with return to normal when potassium was given by mouth. We noted remarkable elongation of oscillatory waves during hypoglycaemia, which we regarded as evidence of increased collateral circulation. It seems that insulin is not the only cause of this increase, probably autogenous adrenaline production, enhanced as a counter regulatory mechanism to insulin, together with the significant fall of serum-potassium, also play a part.

ST PAUL'S CRAY APPOINTMENTS

SIR,—Considerable publicity has been given to Miss Hornsby Smith's statement in the House of Commons alleging that the LCC had "appointed" us to a practice on the St Paul's Cray Estate, and that in doing so had shown us favouritism for political reasons.

In fact, of course, the LCC is entirely unable to appoint general practitioners. Two of us are practising from privately owned houses because the LCC declined to grant us accommodation. The two of us who have LCC houses obtained them only after several other doctors had refused them. These facts must have been known to Miss Hornsby Smith.

We feel quite able to defend ourselves against this remarkable attack, but the unprecedented event of doctors being attacked by name in the House of Commons and their right to their professional positions being questioned solely because of their alleged political views, should evoke an unequivocal reply from the whole profession.

Obituary

NEIL FREDERICK SINCLAIR

F.R.C.S.

Mr Neil Sinclair, surgeon to the West London Hospital, died at his home on Nov 14.

He was born in Jamaica in 1885, the son of Dr F. A. Sinclair. When he arrived in this country fifty years ago, to complete his education, he had few friends and little money. As with so many of the best, his student and early professional life were a struggle. In retrospect he considered this salutary, but there was a note of regret for no one would have enjoyed university life more than he. Yet there remained that great attribute, he was a perpetual student. The London Hospital early became and remained his alma mater. To him it was school college, and university, and he was filled with admiration for it and its great men. He was proud that his son is now a student there.

After qualifying in 1908 he held house-appointments at the London till 1912. He served with the R.A.M.C. in France during the 1914–18 war, and on his return he took his Edinburgh and English surgical fellowships. He went to the West London Hospital as surgical registrar, and he was appointed assistant surgeon in 1919. He quickly built up a busy consulting practice, and he was also on the staff of Chiswick, Northwood, Brentford, and many small hospitals. In 1933 he was appointed surgeon to King George Hospital, Ilford.

The founding of the West London Hospital Medical School gave Sinclair the opportunity for teaching which he welcomed, and his wealth of experience and anecdote made his ward rounds the events of the week. His paternal instincts warmed to his registrars and house-surgeons, and he was a kindly but discriminating patron of younger surgeons. His teaching was conversational, he avoided the lecture-room and preferred to teach at the bedside, in the outpatient department, or in the museum, by gentle control of question and answer, as he had learnt so he taught. He was in fact a great teacher, and his experience and ability were rewarded by his appointment to the court of examiners of the Royal College of Surgeons.

A colleague writes: "Many practitioners relied on Sinclair, and the large number of his doctor patients was a measure of their confidence. It is true they were often kept waiting for his unhurried arrival, but this unpunctuality was essential, almost physiological, in maintaining his health and good spirits, and prevented any tendency to haste in examination of patients, curt-ness to relatives, or operating against the clock. His whole day was theirs, and his working day was a long one."

"Technically his surgery was excellent and a joy to watch, in action quick, yet free from haste, easy, neat, and rhythmical. He liked his instruments to be light and simple, and avoided the 'mechanical' especially among the retractors. By deftness and dexterity he accomplished his high reputation as an operator. It was in the surgery of the thyroid and the upper abdomen that he was a master, by his gentleness shock was prevented and after-treatment minimised."

"We shall remember him as the most friendly robust figure, never pompous, but fiercely jealous of the independence a clinician must command. That he disapproved of many of the changes time have brought is no secret, for his contacts with his colleagues and patients were personal and intimate, and anything that savoured of direction or remote control offended his independent spirit. Dividing as he did, his time between that of his colleagues in hospital and in general practice, no wide gap could develop between them, and, to the

(Thomas Fair)

We consider that it is against the democratic traditions of this country that an irrevocable decision affecting a large segment of the medical profession should be made without any reference to their views on the subject. We would suggest, therefore, that hospital residents and registrars throughout the country should meet to decide their attitude to this proposed change and that the Minister should thereafter take a referendum of their views.

THE PRACTITIONER'S REMUNERATION

SIR,—Your well balanced annotation last week on the proposals of my organisation for a new basis of pay for general practitioners hits the essential nails squarely on the head.

Rightly or wrongly, the Negotiating Body pursued the original general practitioner claims on the basis of a global sum to be divided subsequently as the profession saw fit. This method (which must be unique) has an advantage and a disadvantage—an advantage in that it leaves the distribution of individual doctors' pay to their colleagues, a disadvantage in that the Negotiating Body (G.M.S.C. or Whitley Council) cannot now sue for more money on behalf of an underpaid section as can other bodies of workers.

The argument has resolved itself into one about "betterment". Have the Spens Committee recommendations been sufficiently adjusted to keep pace with the rise in the cost of living since 1938? Of course they have not. All sensible men know this and any economist would confirm it. But is it likely that the Government, in considering the wage claims of any group, will agree to make large scale adjustments dependent on continuous changes in the cost of living? Cabinet Ministers would want £8500 a year instead of the present £5000, M.P.s £1700 instead of £1000, and so on down to the humblest private in the Army. No doubt the G.M.S.C. have an unanswerable case for at least 70%—probably now nearer 90%—increase. The only trouble is that the case will not be answered. The negotiations will be spun out indefinitely (2½ years have already passed and the issues are as confused as ever).

You say that the G.M.S.C. is so sure of the soundness of its case that it does not fear arbitration. The claim is for at least £23 million (including retrospective payment) on behalf of a group whose average net income is not less than £30 per week. I beg leave to doubt whether an arbitration tribunal would grant this claim, and doubting this there is surely a strong case for instituting a claim for the lower paid sections of the profession.

The other important issue is how any extra money should be distributed (whether it is £5 million or £7 million is immaterial). "Redistribution is within the power of the profession itself," you say. Yes, this is indeed true, but it is worth examining the machinery by which the profession exercises these powers. The Annual Conference, which determines policy, derives its power from the democratically elected local medical committees, but how do the latter settle matters of policy? The local representatives are not elected because of any special views they hold, but because they are respected individuals who will guard the practitioners' local interests (the L.M.C. is a statutory body set up for a local purpose). I am not sure whether these committees can decide national policy unless they know the views of the doctors who elected them. But there is no doubt that it is in these committees that such matters should be thrashed out, and it is there that we want the M.P.U.'s scheme discussed. If it is a bad scheme it will get no further. If it is a good one it will be carried to the

Annual Conference and perhaps be adopted as official policy. That is all we ask. In our view this discussion should take place before money is available—not after.

One last point. You ask "Would the M.P.U. council still recommend their new system of remuneration if the Treasury refused to add to the central fund?" I cannot commit my council, but I feel it would answer that this is for the profession to decide. The scheme proposed is not a rigid one, it could be modified in a number of ways. Whether it is modified or rejected, it will have served one purpose if it stimulates discussion. The isolated overworked practitioner has neither the time nor the available data to draw up proposals of this kind. Some central body has to do this for him. We know that our scheme will not please everyone, but it has already elicited a very large number of interesting and important suggestions, as well as much uncritical support.

MEDICAL EDUCATION OF AFRICANS

SIR,—Since 1941 the South African government have awarded five bursaries each year to enable Africans to study medicine at the University of the Witwatersrand, Johannesburg. These were recently discontinued by the present government, but, as the result of protests, the Minister of Education agreed to grant three bursaries for this year and next year only.

The government state that they intend at some future date to reinstate all the bursaries when their proposed non-European medical school is opened in Natal. The indications are, however, that it will be at least another two years before this medical school does in fact open, with a resultant break in the training of sorely needed medical men. The accommodation which is intended for the school consists of a disused army camp near Durban.

The following information from the *Handbook on Race Relations in South Africa*¹ will emphasise the seriousness of the position.

"The present over all ratio (of doctors) is 1 doctor to 3000 population, with variations from 1 to 400 or 500 in the largest urban centres, down to 1 to 30,000 in the more backward rural areas."

"The death rate for Europeans which is slightly less than 10 per 1000 is as low as any in the world, but for non-Europeans it is 20 or over. Other mortality and morbidity rates reflect similar differences between European and non-European. The infant mortality rate for Europeans is less than 50 per 1000 live births, for natives it is not less than 150 anywhere and in some areas as high as 600 or 700. The maternal mortality rates, of 4 to 5 per 1000 births for non-Europeans, is twice as high as for Europeans."

"The incidence of tuberculosis is so high and is rising so rapidly among non-Europeans that it constitutes probably the gravest health problem in the Union today."

South African students, anxious for the future health of the African community and fearing an indirect attack on the university's great tradition of non-segregation, are determined to replace the bursaries which have been removed, and, if possible, to supplement them further.

The students of the Witwatersrand have agreed voluntarily to levy an extra 10s per annum on their fees towards the trust fund which has been set up with the approval of the university authorities. By itself this levy will not be adequate to replace the bursaries, and a public appeal has been launched to obtain donations to supplement the fund.

Each bursary consists of £250 per year for six years and takes the form of a loan, interest free and repayable over a term of years. Thus, once the fund is firmly established it will eventually become self supporting.

¹ Published for the South African Institute of Race Relations by the Oxford University Press, Cape Town and London 1949.

Over and above the amount levied from the students of the Witwatersrand University a sum of £1800 had been collected from the public by the beginning of May this year. Three bursaries have already been awarded for 1950 out of trust fund moneys.

The South African Student Association in London has been appointed representative of the fund in the United Kingdom, and inquiries and donations may be sent to the treasurer, at 46, Napier Court, London, S W 6.

THROMBOANGITIS OBLITERANS TREATED BY HYPOGLYCAEMIA

SIR,—Last year Mazanek¹ reported very favourable results in thromboangitis obliterans treated with hypoglycaemia induced by insulin.

We have applied this treatment in five cases of advanced Buerger's disease, but gave insulin only once a day, with an average of 30–40 administrations in each course. Our patients responded favourably after 1–3 courses, pain disappearing after the first few injections. Circulation of necrotic areas seemed to be accelerated by injections of deoxycortone with vitamin C.

Blood sugar values, which were subnormal in all our cases (56–80 mg per 100 ml.) rose progressively to 116–126 mg per 100 ml at the end of 30 insulin injections (perhaps through stimulation of glucocorticoid hormone production) and did not return to the initial low values after the 20–30 days' interval between two courses.

Electrocardiograms taken half hourly during hypoglycaemic periods showed flattening and inversion of the T wave, especially in V₁, with return to normal when potassium was given by mouth. We noted remarkable elongation of oscillatory waves during hypoglycaemia, which we regarded as evidence of increased collateral circulation. It seems that insulin is not the only cause of this increase, probably autogenous adrenaline production, enhanced as a counter regulatory mechanism to insulin, together with the significant fall of serum potassium, also play a part.

¹ Published for the South African Institute of Race Relations by the Oxford University Press, Cape Town and London, 1949.

Soon after the war he was due to retire, and he was in doubt what life still had in store, when John Ryle invited him to work on industrial lung diseases at the Oxford Institute of Social Medicine. The statistical approach to pathology was novel to him, and the word 'significant' took on a new meaning as he began to classify his records of over 1000 microscopical examinations of lungs. He found Oxford a pleasant place to work in nothing taken for granted and human qualities respected more than elsewhere. As time went on retirement seemed to him another word for getting busier, and he had lately completed the life of John Hunter reviewed on p. 628. In 1948 he was awarded the Weber-Parke prize of the Royal College of Physicians.

Of his continuing and varied appreciation of life, H. W. relates

'When a man who for over ten years has had recurrent pyrexias loses in one night his unique collection of pathological specimens, he might well be soured. But Gloyne's interests never flagged, they seemed sharpened by adversity, the subjects over which his mind ranged widened rather than narrowed. His tenacity of purpose he may have inherited from his Yorkshire forbears, the way in which it was softened by humour and intuition was his own. His views were seldom expressed with Johnsonian bluntness yet there were few subjects on which he could not talk. It was typical that his most intimate friend was a professor of Byzantine history. He read and re-read the English classics, not discursively but one author at a time, from beginning to end. It was as essential to read *Evan Harrington* as to learn all he could from the trials of *Richard Feverel*. His holidays were spent studying the ancient abbeys and he delighted his friends as well as himself by walking them through the Buckinghamshire he knew so intimately, or showing his sympathetic understanding of lord and peasant as he illustrated social history from the top of Bredon Hill.'

Dr. Gloyne is survived by his wife and two children, the daughter an almoner, the son a pathologist.

WILLIAM GLEN LISTON

C.I.E., M.D. GLASG., F.R.C.P.E., F.R.S.E., D.P.H.

Lieut. Colonel Glen Liston, who died at his home at Morar, Inverness-shire, on Oct. 18, was a former director of the Bombay Bacteriological Laboratory at Parel. He will also be remembered for his work as a member of the Plague Research Commission of 1911.

Born in 1873 at Secunderabad, where his father was stationed as an Army chaplain, he was educated at George Watson's College, Edinburgh, and at the Albany Academy, Glasgow. In 1897 he graduated M.B. at Glasgow University and in the following year he entered the Indian Medical Service. During his training course at Netley one of his teachers was Almroth Wright, then professor of pathology at the Army Medical School, and soon after Liston arrived in India in 1893 he was sent to help Wright in the work of the Indian Plague Commission. In 1899 he was transferred to military duties at Ellichpur, in Berar, where he studied malaria, and particularly anopheles mosquitoes, and took part in relief work in the famine of 1899-1900.

In the next year he joined the plague laboratory at Bombay under Haffkine, but he continued his studies on mosquitoes and with the help of Dr. Turkhud prepared detailed drawings of the anopheles found in Berar and Bombay. S. P. James, who was attached to the Royal Society's commission for the study of malaria, was struck with these, he suggested that they should produce a joint work using the drawings prepared by Turkhud and the result was their beautifully illustrated monograph on Indian anopheles.

In their report in 1901 the Royal Commission on Plague virtually rejected L. F. Simond's hypothesis that plague was spread by fleas from plague-infected rats (*Ann. Inst. Pasteur*, October, 1898). But the idea gripped Liston. He at once began studying fleas as he had mosquitoes, and at Netley, where he had lately been appointed to the staff, Almroth Wright gave him every help. On his return to India in 1902 he was posted to the laboratory at Bombay, under Haffkine and Bannerman, and for two years Liston and Bannerman gathered and sifted evidence of the relation of rats and fleas to plague in man—under considerable difficulties, for

Haffkine was failing in health and was subject to curious obsessions which hindered research. An accidental contamination of one phial of the plague vaccine with tetanus, which had happened when Liston was away at Netley, had cast a shadow over the laboratory. The Government of India sought to put matters right by sending Bannerman to Madras, and Liston, much crestfallen and despondent, to Sambalpur as civil surgeon. A few months later both were recalled to the laboratory, and Haffkine was appointed to a special laboratory in Calcutta. Liston's first duty was to reorganise the preparation of the plague vaccine. Maynard's method of bottling was introduced, and the whole procedure, with rigid tests for purity and sterility at every step, was so good that it remained unchanged for the next 25 years.

His important paper on Plague, Rats, and Fleas in the *Indian Medical Gazette* in 1905, which confirmed that "rats are the most important factor in the spread of plague," and gave many observations, his own and others, supporting the view that rat fleas convey plague from rat to rat, from rat to man, and from man to rat, aroused fresh interest in his work. The Secretary of State consulted the Royal Society and the Lister Institute, an advisory committee at home and a working commission in India were set up, and Liston's services were placed at the committee's disposal. When the commission reported, Major George Lamb, the director, pointed out that its work was a coping stone to careful and tedious investigations already carried out in India and elsewhere rather than an original building. In 1907, the commission was temporarily dissolved, Bannerman was promoted surgeon-general and moved to Madras, and Liston became director of the Bombay Bacteriological laboratory. Here every member of his staff could be sure of a patient hearing, encouragement, kindly criticism, and valuable suggestions. The laboratory was several miles from the centre of Bombay, but Liston hardly ever missed a daily visit to one or other of the three large hospitals, and many of the Indian practitioners took their problems to his laboratory.

During the first world war, with a depleted staff, he took charge of a convalescent hospital for infectious diseases, particularly typhoid and paratyphoid fevers, from the army in Mesopotamia, and the laboratory, besides its ordinary work, undertook the search for carriers and their care. After the war he enlarged the laboratory, adding a biochemical unit and a unit for the study of Indian indigenous medicines. He also planned the large modern hospital which now stands next to the laboratory, and he all but succeeded in starting a school for tropical medicine in Bombay. He retired in 1924.

After his return to this country he joined his old Service friends, Colonel W. F. Harvey and Colonel Anderson McKendrick, in Edinburgh at the Royal College of Physicians laboratory as bacteriologist. The Colonial Office appointed him their consulting physician for Scotland. He retired from both these posts in 1947.

MATTHEW BURROW RAY

D.S.O., O.B.E., M.D. EDIN.

The war of 1914-18 sharply divided Dr. Ray's career. The earlier part was largely spent in Yorkshire where, after graduating M.B. from the University of Edinburgh in 1893, he held posts at Eston Hospital and the West Riding Asylum. Later he settled in practice at Harrogate where he joined the staff of the Harrogate Infirmary and laid the basis of his practical knowledge of hydrotherapy. As anthropologist to the Wellcome expedition, he visited the Sudan, and in 1913 at the International Congress of Medicine he described human remains he had examined in an Ethiopian cemetery.

During the 1914-18 war he had a distinguished military record. For his services as officer in charge of No. 3 casualty clearing station and as senior medical officer at Amiens he was appointed D.S.O. in 1917 and mentioned in despatches. Later with the rank of colonel he became A.D.M.S. 47th (2nd London) Division of the Territorial Army.

After he was demobilised Dr. Ray settled in London. "In the early twenties," writes C. B. H., "Ray worked with the late Dr. Fortescue Fox to secure for London a treatment centre in rheumatism and arthritis that would

patient's benefit, there resulted that essential, continuity of treatment. Very many will have read of his death with sorrow. Not only was he from so many aspects, the ideal practical surgeon, but he had so many friends and acquaintances in the profession that the directory seemed only required to confirm his information."

STEPHEN RODHOUSE GLOYNE

M D LEEDS, D P H

Dr Gloyne, who died on Sept 25, aged nearly 68, was a Yorkshireman—stocky, matter of fact, sociable—who made his mark in London as a student and interpreter of respiratory disease. Though he was born at Peckham his parents soon returned to Yorkshire, and he went to school at Wakefield and studied medicine at the Yorkshire College before entering the Middlesex Hospital, where he worked for a year or two in the pathology department after qualification. In 1906 he took the first M.B. degree granted by the new University of Leeds, and in 1909 he proceeded to the degree of M.D. Meanwhile he had returned to London, taking appointments as assistant school medical officer to the L.C.C. and later to the East Sussex county council.

In 1911 he moved northwards to Victoria Park, where, as pathologist to the London Chest Hospital, he

worked till 1948. During these years he attained without conscious effort a unique place in the life of the hospital. It was difficult to think of Victoria Park without also thinking of Gloyne. His laboratory became a museum and reference library, the rendezvous of the clinical staff, and a centre for teaching and research. Letters from his friends give a vivid picture of his qualities as a counsellor and a friend.

J. I. writes: "When Gloyne took up his appointment at Victoria Park the department was one room to the right of

the front door of the hospital, and I do not think that any of us would have forecast the splendid department that developed from that modest beginning. Nor would we have expected Gloyne to have been the man to effect that development. He was no thruster, and at that time we little realised the force that lay beneath his quiet unassuming manner. A friend of many generations of residents, he came to be considered as the one constant member of a changing staff, and it was to him we went for news of the hospital. He had a very deep affection for Victoria Park Hospital and to do any service for it or for anyone connected with it gave him real pleasure. He was one of those lovable men who, maintaining a very high standard for themselves, yet are very tolerant and sympathetic to the weakness of their fellows. I have never known him speak unkindly of anyone. In spite of his fundamental seriousness he was full of quiet humour. He was a delightful companion and a staunch friend."

H. W. takes up the tale: "During the 1914-18 war, he combined the rôles of house physician, pathologist, and consultant rolled into one modest Posh Bah, the only regular doctor in the place. What he gained in clinical acumen and intuitive understanding from that grim experience will never be known."

N. L. R. continues: "It is in the comparatively spacious and tranquil days between the wars that those who knew Gloyne best will perhaps picture him most easily. It is pleasant to be able to remember those after lunch gatherings which became a forum of debate where the most junior pitted his talents against such masters as Freddie Chandler, Burton Wood, and V. S. Hodson. Gloyne excelled on these occasions. It mattered little whether the subject under discussion was a clinical problem, a knotty point of history, or a character from English literature, he, as like as not, from his habitual seat at the end of the sofa, would put the matter in its right perspective or when as sometimes, happened

political sparks began to fly, he would, with his characteristic infectious laugh, disperse us all to outpatients in the best of humours. It is in this setting that we shall remember him—a scholar with wide interests, a fine pathologist and yet no mean clinician, but above all as one of the most lovable of men."

During the late war, when the hospital suffered severely at the hands of the enemy, and by the death of two senior members of its staff, Gloyne again came forward and shouldered a burden which perhaps no one else could have borne. The loss in one night in 1941 of his laboratory, his museum specimens, and his new microscope he rarely mentioned. Instead he turned his thoughts at once to the hospital and its responsibilities. He and his wife placed their cottage in the country at the disposal of the matron as a rest centre for the nurses, and he played a prominent part in opening the country branch at Camberley. He was also an E.M.S. pathologist at St Margaret's Hospital, Epping.

Among his colleagues in other specialties which marched with his own Gloyne made an equally lasting impression. Of his work outside Victoria Park E. L. O. reports:

"Two things were near to the heart of Gloyne and to both he gave of his best—and his best was good indeed. One was the journal, *Tubercle*. He superintended it from its inception and thereafter steered it through many perilous passages. And the more perilous the passage, the more, under his direction, did the journal emerge with enhanced status. The second was his interest in pulmonary diseases due to dust. He was among the first to recognise the unexpected toxicity of asbestos dust at a time when others were only prepared to accept silica dust as harmful. His studies will always be regarded as opening the door to the disease entity known as asbestosis. He approached it especially from the clinical and histological aspects without relying too much on X-ray shadows. He told of what he had observed and his observations were always confirmed by others."

N. H. S., a fellow pathologist, writes: "For a great many years he was the only pathologist of any authority connected with thoracic work as a specialty. His investigations were practical in intent and within the range of an ordinary hospital laboratory, and his experimental work though simple in design showed that he could have done pure research just as successfully had he so chosen. His output in print is no measure of his learning. But his writing was concise, accurate, beautifully illustrated, and extremely valuable to those of us with the same interests."

Gloyne's influence was acknowledged in the field of industrial medicine. He was a part time member of the Medical Board for Silicosis and Asbestosis from 1931 till 1948, and his colleague C. S. writes:

"Although the amount of work Gloyne did for the board was not large, the personal influence he brought made his contribution of the greatest importance. His profound knowledge of the pathological processes produced by dust, and his kindly method of showing it, stimulated the interest of all his colleagues, and his work on asbestosis made him for us the acknowledged authority on this form of pneumoconiosis."

As president of the Tuberculosis Association and Thoracic Society Gloyne's prestige and popularity were enhanced by the clear sanity and common sense of his remarks.

"He saw many changes in tuberculosis and chest work and recognised their worth and future value with uncanny accuracy," writes T. H. S. "His professional life was centred round the chest hospitals which he elected to serve in preference to higher academic posts, but his influence extended far beyond the bounds of thoracic pathology. And anyone who met Stephen Gloyne more than once cannot but have been impressed by the essential goodness of the man. In these days it is rare to find a man who had so many friends and admirers. The active little figure, white headed almost as long as I can remember acted as adviser and father confessor to the many who approached him with their problems. His counsel was kind and always helpful, though his comments were not devoid of a tinge of caustic wit—the bitter sweet that could often act as a spur or corrective."

Soon after the war he was due to retire, and he was in doubt what life still had in store, when John Ryle invited him to work on industrial lung diseases at the Oxford Institute of Social Medicine. The statistical approach to pathology was novel to him, and the word "significant" took on a new meaning as he began to classify his records of over 1000 microscopical examinations of lungs. He found Oxford a pleasant place to work in nothing taken for granted and human qualities respected more than elsewhere. As time went on retirement seemed to him another word for getting busier, and he had lately completed the life of John Hunter Parkes on p. 628. In 1948 he was awarded the Weber-Parkes prize of the Royal College of Physicians.

Of his continuing and varied appreciation of life, H. W. relates

"When a man who for over ten years has had recurrent pyrexias loses in one night his unique collection of pathological specimens, he might well be soured. But Gloyne's interests never flagged, they seemed sharpened by adversity, the subjects over which his mind ranged widened rather than narrowed. His tenacity of purpose he may have inherited from his Yorkshire forebears, the way in which it was softened by humour and intuition was his own. His views were seldom expressed with Johnsonian bluntness yet there were few subjects on which he could not talk. It was typical that his most intimate friend was a professor of Byzantine history. He read and re-read the English classics not discursively, but one author at a time, from beginning to end. It was as essential to read *Evan Harrington* as to learn all he could from the trials of *Richard Feterel*. His holidays were spent studying the ancient abbeys and he delighted his friends as well as himself by walking them through the Buckinghamshire he knew so intimately, or showing his sympathetic understanding of lord and peasant as he illustrated social history from the top of Bredon Hill."

Dr Gloyne is survived by his wife and two children, the daughter an almoner, the son a pathologist.

WILLIAM GLEN LISTON

C.I.E., M.D. GLASG., F.R.C.P.E., F.R.S.E., D.P.H.

Lieut. Colonel Glen Liston, who died at his home at Morar, Inverness shire, on Oct. 18, was a former director of the Bombay Bacteriological Laboratory at Parel. He will also be remembered for his work as a member of the Plague Research Commission of 1911.

Born in 1873 at Secunderabad, where his father was stationed as an Army chaplain, he was educated at George Watson's College, Edinburgh, and at the Albany Academy, Glasgow. In 1897 he graduated M.B. at Glasgow University and in the following year he entered the Indian Medical Service. During his training course at Netley one of his teachers was Albroth Wright, then professor of pathology at the Army Medical School, and soon after Liston arrived in India in 1898 he was sent to help Wright in the work of the Indian Plague Commission. In 1899 he was transferred to military duties at Ellichpur, in Berar, where he studied malaria, and particularly anopheles mosquitoes, and took part in relief work in the famine of 1899-1900.

In the next year he joined the plague laboratory at Bombay under Haffkine, but he continued his studies on mosquitoes and with the help of Dr. Turkhud prepared detailed drawings of the anopheles found in Berar and Bombay. S. P. James, who was attached to the Royal Society's commission for the study of malaria, was struck with these, he suggested that they should produce a joint work using the drawings prepared by Turkhud, and the result was their beautifully illustrated monograph on Indian anopheles.

In their report in 1901 the Royal Commission on Plague virtually rejected L. F. Simond's hypothesis that plague was spread by fleas from plague infected rats (*Ann. Inst. Pasteur*, October, 1898). But the idea gripped Liston. He at once began studying fleas as he had mosquitoes, and at Netley, where he had lately been appointed to the staff, Albroth Wright gave him every help. On his return to India in 1902 he was posted to the laboratory at Bombay, under Haffkine and Bannerman, and for two years Liston and Bannerman gathered and sifted evidence of the relation of rats and fleas to plague in man—under considerable difficulties, for

Haffkine was failing in health and was subject to curious obsessions which hindered research. An accidental contamination of one phial of the plague vaccine with tetanus, which had happened when Liston was away at Netley, had cast a shadow over the laboratory. The Government of India sought to put matters right by sending Bannerman to Madras, and Liston, much crestfallen and despondent, to Sambalpur as civil surgeon. A few months later both were recalled to the laboratory, and Haffkine was appointed to a special laboratory in Calcutta. Liston's first duty was to reorganise the preparation of the plague vaccine. Maynard's method of bottling was introduced, and the whole procedure, with rigid tests for purity and sterility at every step, was so good that it remained unchanged for the next 25 years.

His important paper on Plague, Rats, and Fleas in the *Indian Medical Gazette* in 1905, which confirmed that "rats are the most important factor in the spread of plague," and gave many observations, his own and others', supporting the view that rat fleas convey plague from rat to rat, from rat to man, and from man to rat, aroused fresh interest in his work. The Secretary of State consulted the Royal Society and the Lister Institute, an advisory committee at home and a working commission in India were set up, and Liston's services were placed at the committee's disposal. When the commission reported, Major George Lamb, the director, pointed out that its work was a coping stone to careful and tedious investigations already carried out in India and elsewhere rather than an original building. In 1907, the commission was temporarily dissolved, Bannerman was promoted surgeon-general and moved to Madras, and Liston became director of the Bombay Bacteriological Laboratory. Here every member of his staff could be sure of a patient hearing, encouragement, kindly criticism, and valuable suggestions. The laboratory was several miles from the centre of Bombay, but Liston hardly ever missed a daily visit to one or other of the three large hospitals, and many of the Indian practitioners took their problems to his laboratory.

During the first world war, with a depleted staff, he took charge of a convalescent hospital for infectious diseases, particularly typhoid and paratyphoid fevers, from the army in Mesopotamia, and the laboratory, besides its ordinary work, undertook the search for carriers and their care. After the war he enlarged the laboratory, adding a biochemical unit and a unit for the study of Indian indigenous medicines. He also planned the large modern hospital which now stands next to the laboratory, and he all but succeeded in starting a school for tropical medicine in Bombay. He retired in 1924.

After his return to this country he joined his old Service friends, Colonel W. F. Harvey and Colonel Anderson McKendrick, in Edinburgh at the Royal College of Physicians laboratory as bacteriologist. The Colonial Office appointed him their consulting physician for Scotland. He retired from both these posts in 1947.

MATTHEW BURROW RAY

D.S.O., O.B.E., M.D. EDN.

The war of 1914-18 sharply divided Dr Ray's career. The earlier part was largely spent in Yorkshire where, after graduating M.B. from the University of Edinburgh in 1893, he held posts at Eston Hospital and the West Riding Asylum. Later he settled in practice at Harrogate where he joined the staff of the Harrogate Infirmary and laid the basis of his practical knowledge of hydrotherapy. As anthropologist to the Wellcome expedition he visited the Sudan, and in 1913 at the International Congress of Medicine he described human remains he had examined in an Ethiopian cemetery.

During the 1914-18 war he had a distinguished military record. For his services as officer in charge of No. 3 casualty clearing station and as senior medical officer at Amiens he was appointed D.S.O. in 1917 and mentioned in despatches. Later with the rank of colonel he became A.D.M.S. 47th (2nd London) Division of the Territorial Army.

After he was demobilised Dr Ray settled in London. In the early twenties writes C. B. H., Ray worked with the late Dr. Fortescue Fox to secure for London a treatment centre in rheumatism and arthritis that would

be a credit. When these labours came to a successful end, by the formation of the British Red Cross Clinic for Rheumatism, Dr Ray was appointed the first honorary physician. Thereafter for a long period he gave loyal and steadfast service that set a fine example to his medical colleagues, and was of great benefit to the staff and patients at this unit. In 1948 he was appointed OBE in recognition of this service. He continued to work at the clinic till in 1948, on the introduction of the National Health Service, it was attached to the Middlesex Hospital as the Arthur Stanley Institute for Rheumatic Diseases. He was also physician and director of the department of physiotherapy at the St Marylebone and Westminster General Dispensary. His publications include *Rheumatism in General Practice* (1934), which gave a general survey of the disease and a review of its several manifestations in different regions of the body, and *Hydrotherapy and Climatotherapy* (1936) in which he classified and described spas at home and abroad in accordance with their main therapeutic indications. His mind was both vigorous and versatile. His pictures shown at exhibitions of the Medical Art Society will be remembered for their individuality, and he was an expert in cabinet making.

Dr Ray is survived by his widow, Edith, daughter of the late Lord Henry Cholmondeley and widow of Captain R. E. Heaven. He died in London on July 5 at the age of 80.

AMY FLORENCE WAKLEY

THE only daughter of Thomas Henry Wakley (joint editor of THE LANCET from 1886 to 1905) and eldest grand daughter of Thomas Wakley (founder, and editor from 1823 to 1862) died at Burwash, Sussex, on Nov. 14. Her father lived to be senior fellow of the Royal College of Surgeons, and she herself was in her 95th year when she died, the three generations, from the birth of Thomas Wakley in 1795, spanned between them a century and a half. She was small and spirited, full of the family wit, and is said to have kept track of the large and growing company of Wakleys and of those who are connected with them. Many of her kin came to her funeral service, some meeting as old friends and some as young strangers. This hardy strain, deriving from Devon farmers, inherits the vitality which made Thomas Wakley an outstanding character.

Births, Marriages, and Deaths

BIRTHS

CAPON—On Nov. 13, at Plymouth the wife of Dr J. H. Capon—a son.
LAURANCE—On Nov. 11, in London the wife of Dr B. M. Laurance—a son.
PAULLEY—On Nov. 10, at Woodbridge, to Dr Deirdre Paulley (née Gavin Jones) wife of Dr J. W. Paulley—a son.
PINSON—On Nov. 14, in London, the wife of Dr K. D. Pinson—a daughter.
ROSS—On Nov. 13, in London, the wife of Dr John Ross—a daughter.
TAYLOR—On Nov. 18, in London the wife of Mr Selwyn Taylor—a daughter.
TODD—On Nov. 8, in London to Dr Olive Todd wife of Dr K. R. Todd—a daughter.
YOUNG—On Nov. 9, at Macclesfield, the wife of Dr F. R. Mackinlay Young—a son.

MARRIAGES

BENNETT—BALDWIN—On Nov. 15, at Colwyn Bay, F. J. Bennett, M.B. to Jessie Baldwin.

DEATHS

CARLING—On Nov. 15, at Alton Hants William Carling M.B. Camb aged 88.
CLARK—On Nov. 15, in Glasgow John Sawers Clark, M.C. M.A. M.D. Glasg. D.P.H.
FINSTERBUSH—On Nov. 15, at Reading Edmund Finsterbush M.D. Vienna.
HARLEY—On Nov. 13, in London Thomas William Harley, C.I.E. M.B. Dubl. Lieut.-colonel I.M.S. ret'd.
LOW—On Nov. 15, Alexander Low M.A. M.D. LL.D. Aberd. aged 82.
SINCLAIR—On Nov. 14, in London, Neil Frederick Sinclair F.R.C.S. F.R.C.S.E.
SMITH—On Nov. 16, at Markyate Herts James Ernest Sutcliffe Smith M.B. Lond., aged 73.
SWAFFIELD—On Nov. 19, in London, Walter Henry Swaffield, M.D. Edin. F.R.C.S.E.
WADE—On Nov. 15, at Enfield Middlesex Herbert Wade M.R.C.S. aged 87.

Notes and News

MORE BEDS FOR THE AGED SICK

THE St Pancras branch of University College Hospital has, for the last two years, devoted 120 beds to the treatment of the aged sick. Experience has shown that a certain proportion of these beds become blocked by patients whose treatment is complete, but who cannot be discharged, either because they have no home to go to or because of some residual disability which requires nursing care. With the help of a substantial grant from King Edward's Fund, the geriatric unit has now acquired a house in Highgate, to be known as the Thomas Barlow Home, where 30 patients will be accommodated under the supervision of the unit physicians. Some may be expected to remain for very long periods, but others will be discharged when alternative arrangements can be made. The precious—and costly—beds which they vacate at St Pancras will be occupied by some of the aged sick now waiting for admission whose treatment requires the facilities and resources which only a fully equipped hospital possesses.

LONDON'S HOSPITALS AT A GLANCE

A NEW map of the London hospitals has been prepared by King Edward's Hospital Fund¹ to supersede the one they published in 1944, when the N.H.S. was still no more than a twinkle in Mr Willink's eye. They have had a much harder task this time, but have succeeded in presenting the large amount of complex information with the help of four colours, a fine variety of symbols, and some connecting lines. The map shows the location, function, and ownership of all the hospitals in the Metropolitan Police area, how they are grouped under management committees, and the boundaries between the territories of the regional boards. The hospital map proper is superimposed on an Ordnance Survey map printed lightly enough to avoid interfering with the essential symbols but perhaps not quite darkly enough to tell strangers where they are. It might have been better to include only the river, main landmarks, and a few major roads. Nevertheless the whole effect is not only clear but decorative. An alphabetical index and a classified index, bound into a little booklet, are supplied as a key to the map.

THE CHILD AND THE FILM

THE cinema, with its mixture of values, good, bad, and mediocre, and its large claims on the national time and attention, can be regarded either as a telescope sweeping the horizons of the world or a microscope magnifying criminal behaviour—a fount of education or a device for corrupting morals—depending on the outlook of the critic. The idea that it must be largely responsible for the rise in juvenile delinquency is widely held, though mainly by those who are not regular cinema goers. The Departmental Committee on Children and the Cinema,² which reported last May, concluded (with one dissentient) that the evidence as a whole did not "fasten on the cinema any primary share of responsibility for delinquency or moral laxity of children under 16." What secondary share it may have must be a matter of conjecture. Some think it instructs children in methods of crime, others that it glorifies brutality and equates success with money getting, others that trouble is caused not by the cinema but by the need to get the money to go.

The committee based many of their conclusions on the results of an inquiry made by the Social Survey during 1948, and these results have just been published.³ Though they add nothing new, they give a more detailed picture than the committee's report, and deserve study. It will be remembered that the committee recommended a new classification of films to replace the current classification of "U" (for universal exhibition), "A" (for exhibition to adult audiences), and "H" (horrific films, for exhibition when no children under 16 are present). These categories are admittedly unsatisfactory, because a child can see an "A" film provided he is accompanied by an adult and in Scotland he can see "H" films too. The Social Survey found that of the children who

had been to the cinema in the week before they were interviewed, about a third had seen only "U" films, nearly half had seen "A" films only, and about a sixth had seen some of each. The departmental committee favoured four different classifications "X" films (to include the present "H" category) from which children should be absolutely excluded, "C" films, to be shown at children's cinema exhibitions, advisory category "U," for family entertainment, and advisory category "A," preferably for adults. Admission of children to the last two categories would be unrestricted.

Whether these reasonable recommendations are to be put into action or not, the time has almost certainly come to review the criteria on which films are classed as suitable or unsuitable for children. In a recent programme *Captain Boycott*, a film dealing with the conquest of injustice by peaceful means, was classed as "A", while the trailer for a forthcoming "U" film showed savage fighting, machine gunning, and other scenes of violence.

NEW BRITISH STANDARDS

THE British Standards Institution has issued new standards for hospital bedsteads for general purposes (B.S. 1082/1950), and for paper boxes for pills, tablets, ointments, pastes, creams powder and crystals (B.S. 1679/1950).

The bedstead is of tubular steel construction and is 6 ft. 6 in. long by 3 ft. wide with the spring mattress at 2 ft. from the floor. Provision is also made for bedsteads which are 6 ft. 9 in. or 7 ft. long, together with alternative heights of 2 ft. 3 in. or 2 ft. 6 in. The standard includes a specification for a removable lifting pole and provides for the inclusion of adjustable back rests and wheeling devices.

Copies of these standards (bedsteads 2s. 6d., paper boxes 1s.) may be obtained from the institution's sales department, 24 Victoria Street, London, S.W. 1.

University of Oxford

On Nov. 18, the honorary degree of D.Sc. was conferred on Dr. Oscar Vogt, director of the Berlin Institute for Brain Research.

University of Cambridge

On Nov. 11 the degree of M.B. was conferred on S. E. Birdsall.

University of Bristol

At a recent examination for part II of the D.M.B.D. J. B. Fox and Zbigniew Lachowicz were successful.

University of Birmingham

The title of reader in medicine has been conferred on Dr. K. W. Donald, and of reader in surgery on Mr. B. N. Brooke. Dr. M. B. Conran has been appointed lecturer in bacteriology and Dr. K. Aterman lecturer in biophysics. The following clinical lecturers have been appointed:

Obstetrics—Dr. Jean Hallam Dr. G. S. Lester Dr. L. M. Park.
Radiology—Dr. J. Bishop Mr. W. H. Bond Dr. O. E. Smith.
Dental Surgery—Dr. R. F. Pusey B.D.S.

Mr. J. A. Stallworthy has been appointed Ingleby lecturer for 1951. Prof. Edward D. Churchill, chief of the general surgical services, Massachusetts General Hospital, Boston, will take part in the surgical work of the teaching hospitals during the spring term.

On Nov. 21 a hostel, which will accommodate 12 students while they are doing their midwifery training, was opened at Dudley Road Hospital. It is to be called the Hilda Lloyd Hostel.

Scottish Conjoint Board

At recent examinations for licentiatehip of the Royal Colleges of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow the following were successful:

W. St. C. Bauld T. L. Bowden Wilfred Brabbin, Louis Brinberg, J. P. Capel Simon Caplan J. T. Davidson J. W. Davison, Donald Duck Ruth M. Eaton R. Y. Forbes, Isabel M. Forster Marshall Frieze K. M. Graham J. G. Green A. I. Hutchinson J. L. W. Johnson Anna M. M. Lepper Veronica R. E. Lethbridge T. J. McCabe R. H. G. McKay I. T. McLachlan A. M. Muir, Denis Murray P. A. O'Brien Arthur Pollack, Anne McK. Rodger Bertram Schulberg Harebrun Bunsee Singh P. I. Sless B. D. A. Smith Leslie Steen I. S. Trotter E. G. C. Valerio.

McGill University

Dr. Eric Wittkower has been appointed assistant professor of psychiatry. He will take up his appointment in Montreal next March.

University of London

At recent examinations the following were successful:

V. B. S.—David Burman M. W. Cernlyn Jones P. J. Chapman S. S. Epstein D. I. Fryer L. G. Goodwin P. E. B. Holmes, C. B. Ingor Willey R. P. V. Jayewardene R. S. Jelliffe, *D. J. * University medal

Royal Institute of Public Health and Hygiene

On Monday Tuesday, and Wednesday Dec. 11, 12, and 13, at 4.30 p.m., at 28, Portland Place, London, W. 1, Sir Leonard Parsons F.R.S., will deliver the Harben lectures, entitled *Studies on Child Health*.

International Course on Child Psychiatry

On Nov. 12 some 30 psychiatrists, paediatricians, and social workers from 19 countries in Europe the Middle East, and Latin America began a course on this subject in London. Their programme was arranged by the British Council, with Dr. Kenneth Soddy and Dr. Emanuel Miller as advisers, and it forms part of a course arranged by the Centre International de l'Enfance the first part of which was held in Paris.

British Congress of Obstetrics and Gynaecology

At this congress, which is to be held at Leeds from July 8 to 11, 1952 the following subjects have been chosen for discussion: abnormal uterine action in labour, stress incontinence of urine, the place of the paediatrician in a maternity unit, and genital tuberculosis in the female. The secretary of the congress is Mr. B. L. Jeaffreson, 32, Park Square, Leeds, 1.

Faculty of Ophthalmologists

At a meeting of the council on Oct. 13, it was reported that the following committee had been recognised by the Minister of Health to deal with future admissions to the Central Professional Committee's list of ophthalmic medical practitioners. The Hon. G. J. O. Bridgman Mr. Nigel Cridland, Mr. N. P. R. Galloway, Mr. J. J. Healy, Mr. H. B. Ingram, and Mr. E. G. Mackie. It was agreed to ask the faculty's representatives to propose that no ophthalmic medical practitioner should be admitted to the list unless he held a contract with a hospital, from S.H.O. grade upwards, and that if he relinquished his post he should cease to be included on the list.

be a credit. When these labours came to a successful end, by the formation of the British Red Cross Clinic for Rheumatism, Dr Ray was appointed the first honorary physician. Thereafter for a long period he gave loyal and steadfast service that set a fine example to his medical colleagues, and was of great benefit to the staff and patients at this unit. In 1948 he was appointed OBE in recognition of this service. He continued to work at the clinic till in 1948, on the introduction of the National Health Service, it was attached to the Middlesex Hospital as the Arthur Stanley Institute for Rheumatic Diseases. He was also physician and director of the department of physiotherapy at the St Marylebone and Westminster General Dispensary. His publications include *Rheumatism in General Practice* (1934), which gave a general survey of the disease and a review of its several manifestations in different regions of the body, and *Hydrotherapy and Climatotherapy* (1936) in which he classified and described spas at home and abroad in accordance with their main therapeutic indications. His mind was both vigorous and versatile. His pictures shown at exhibitions of the Medical Art Society will be remembered for their individuality, and he was an expert in cabinet-making.

Dr Ray is survived by his widow, Edith, daughter of the late Lord Henry Cholmondeley and widow of Captain R E Heaven. He died in London on July 5 at the age of 80.

AMY FLORENCE WAKLEY

THE only daughter of Thomas Henry Wakley (joint editor of THE LANCET from 1886 to 1905) and eldest grand-daughter of Thomas Wakley (founder, and editor from 1823 to 1862) died at Burwash, Sussex, on Nov 14. Her father lived to be senior fellow of the Royal College of Surgeons, and she herself was in her 95th year when she died, the three generations, from the birth of Thomas Wakley in 1705, spanned between them a century and a half. She was small and spirited, full of the family wit, and is said to have kept track of the large and growing company of Wakleys and of those who are connected with them. Many of her kin came to her funeral service, some meeting as old friends and some as young strangers. This hardy strain, deriving from Devon farmers, inherits the vitality which made Thomas Wakley an outstanding character.

Births, Marriages, and Deaths

BIRTHS

- CAPON—On Nov 13 at Plymouth, the wife of Dr J H Capon—a son.
LAURANCE—On Nov 11 in London, the wife of Dr B M Laurance—a son.
PAULLEY—On Nov 10 at Woodbridge to Dr Deirdre Paulley (née Gavin Jones) wife of Dr J W Paulley—a son.
PINSON—On Nov 14 in London the wife of Dr K D Pinson—a daughter.
ROSS—On Nov 13, in London, the wife of Dr John Ross—a daughter.
TAYLOR—On Nov 18 in London the wife of Mr Selwyn Taylor F.R.C.S.—a daughter.
TODD—On Nov 8 in London to Dr Olive Todd, wife of Dr K R Todd—a daughter.
YOUNG—On Nov 9 at Macclesfield the wife of Dr F R Mackinlay Young—a son.

MARRIAGES

- BENNETT—BALDWIN—On Nov 15 at Colwyn Bay F J Bennett, M.B. to Jessie Baldwin.

DEATHS

- CARLING—On Nov 15 at Alton Hants William Carling M.B. Camb aged 88.
CLARK—On Nov 15 in Glasgow John Savers Clark M.C. M.A. M.B. Glasg., D.P.H.
FINSTERBUSH—On Nov 15 at Reading Edmund Finsterbush M.D. Vienna.
HARLEY—On Nov 13 in London Thomas William Harley C.I.E. M.B. Dubl. Hon. colonel I.M.S. ret'd.
LOW—On Nov 15 Alexander Low M.A. M.D. LL.D. Aberd., aged 82.
SINCLAIR—On Nov 14 in London, Neil Frederick Sinclair F.R.C.S. F.R.C.S.E.
SMITH—On Nov 16 at Markyate Herts, James Ernest Sutcliffe Smith M.B. Lond., aged 73.
SWAFFIELD—On Nov 19 in London, Walter Henry Swaffield M.D. Edin., F.R.C.S.F.
WADE—On Nov 15 at Enfield Middlesex Herbert Wade M.R.C.S. aged 87.

Notes and News

MORE BEDS FOR THE AGED SICK

THE St Pancras branch of University College Hospital has, for the last two years, devoted 120 beds to the treatment of the aged sick. Experience has shown that a certain proportion of these beds become blocked by patients whose treatment is complete, but who cannot be discharged, either because they have no home to go to or because of some residual disability which requires nursing care. With the help of a substantial grant from King Edward's Fund, the geriatric unit has now acquired a house in Highgate, to be known as the Thomas Barlow Home, where 30 patients will be accommodated under the supervision of the unit physicians. Some may be expected to remain for very long periods, but others will be discharged when alternative arrangements can be made. The precious—and costly—beds which they vacate at St Pancras will be occupied by some of the aged sick now waiting for admission whose treatment requires the facilities and resources which only a fully equipped hospital possesses.

LONDON'S HOSPITALS AT A GLANCE

A NEW map of the London hospitals has been prepared by King Edward's Hospital Fund¹ to supersede the one they published in 1944, when the N.H.S. was still no more than a twinkle in Mr Willink's eye. They have had a much harder task this time, but have succeeded in presenting the large amount of complex information with the help of four colours, a fine variety of symbols, and some connecting lines. The map shows the location, function, and ownership of all the hospitals in the Metropolitan Police area, how they are grouped under management committees, and the boundaries between the territories of the regional boards. The hospital map proper is superimposed on an Ordnance Survey map printed lightly enough to avoid interfering with the essential symbols but perhaps not quite darkly enough to tell strangers where they are. It might have been better to include only the river, main landmarks, and a few major roads. Nevertheless the whole effect is not only clear but decorative. An alphabetical index and a classified index, bound into a little booklet, are supplied as a key to the map.

THE CHILD AND THE FILM

THE cinema, with its mixture of values, good, bad, and mediocre, and its large claims on the national time and attention, can be regarded either as a telescope sweeping the horizons of the world or a microscope magnifying criminal behaviour—a fount of education or a device for corrupting morals—depending on the outlook of the critic. The idea that it must be largely responsible for the rise in juvenile delinquency is widely held, though mainly by those who are not regular cinema goers. The Departmental Committee on Children and the Cinema,² which reported last May, concluded (with one dissentient) that the evidence as a whole did not "fasten on the cinema any primary share of responsibility for delinquency or moral laxity of children under 16." What secondary share it may have must be a matter of conjecture: some think it instructs children in methods of crime, others that it glorifies brutality and equates success with money getting, others that trouble is caused not by the cinema but by the need to get the money to go.

The committee based many of their conclusions on the results of an inquiry made by the Social Survey during 1948, and these results have just been published.³ Though they add nothing new, they give a more detailed picture than the committee's report, and deserve study. It will be remembered that the committee recommended a new classification of films to replace the current classification of "U" (for universal exhibition), "A" (for exhibition to adult audiences), and "H" (horrific films, for exhibition when no children under 16 are present). These categories are admittedly unsatisfactory, because a child can see an "A" film provided he is accompanied by an adult and in Scotland he can see "H" films too. The Social Survey found that of the children who

THE PATIENT AND HIS DISEASE *

A E CLARK-KENNEDY
M.D. Camb, F.R.C.P.PHYSICIAN TO THE LONDON HOSPITAL AND DEAN OF THE
MEDICAL SCHOOL, FELLOW OF CORPUS CHRISTI COLLEGE,
CAMBRIDGE

I HAVE not made any particular contribution to medicine which I can now take the opportunity to expound as Dr William Croone would have wished I, therefore propose, although I fully realise how ill qualified I am to make the attempt, to paint in these two lectures a picture of medicine as a single undivided whole. That I shall appear superficial is inevitable, too theoretical for your liking probable I shall be tedious; telling you nothing new, merely gathering up the strands and tying together the loose ends of our existing knowledge. But I am so convinced of the need for a general concept on which we can to some extent agree that I am impelled to try. Without it, we run a grave risk of losing touch with one another. Moreover, our vision of the whole is tending to be obscured more and more by the increasing amount of technical knowledge which we must each acquire.

Body and Mind

The ordinary man, student or teacher, doctor or patient, thinks of himself (when he is not attempting to argue metaphysics) as a body and mind, the former as something which he can see and feel, the latter as something intangible and yet as something of which he is absolutely certain "I think, therefore I am" was the starting point of the Cartesian system of philosophy. But what is body and what is mind? What is the relationship between them? What attitude to these problems should the doctor adopt? These questions must be answered, in so far as they can be answered, I think, at the start.

Science, organised common sense, teaches that the human body is the product of the plan laid at its conception and the environment in which it develops. It is often compared to a machine the design of which is the result of deliberate thought directed towards a certain end. But the design of the human body is the result of mutation and natural selection in the course of organic evolution. A machine must be copied. But the general design of the body is inherited. Machines are turned out to a standard pattern. Bodies differ slightly, their individual details being largely determined by the chance mating of two people of opposite sex, and then, according to genetic theory, by the chance union of two gametes and the reshuffling of the genes. The execution of a plan for a machine depends on deliberate action. The plan for a human body executes itself. A machine has to be actively maintained. A human body, kept supplied with the necessary materials, maintains its characteristic form and function, as predestined in the plan whence it was derived, and continues to convert chemical energy into heat and the kinetic energy of movement. In fact the human machine differs fundamentally from the machines of man's invention. It is alive, self-developing and self-maintaining, self-repairing and self-reproducing. Moreover, it maintains a system of high energy content in a world in which the general tendency is in the direction of the dissipation of energy. It permits the development and maintenance of consciousness and mind.

Consciousness appears to depend in some way on the brain which is part of the body. The development of

the mind under the stimulus of experience seems to be conditioned by the physiological characteristics of the brain. (The individual mind, therefore, like the individual body, depends to some extent on chance.) According to one view consciousness and mind are both epiphenomena of matter. The brain is said to make consciousness, in much the same sense that the heart circulates the blood, and the reactions of the mind are said to be determined by physicochemical changes in the brain. But if all human behaviour was determined by conditioned reflexes, consciousness, which allows of pain and pleasure, and permits the development of the conscious mind which asks the question, would still remain mysterious. Materialism leaves the "I think, therefore I am," the certainty of self, entirely unexplained. Moreover 20th-century physics has reduced the extension of concrete objects in space and time to conceptions of the mind, while modern physiology compels the conclusion that their sensory qualities, which we unthinkingly attribute to them in their own right, are really added by the human nervous system. Idealism, however, is unsatisfactory. It conceives that all physical events take place in mind, which is contrary to common sense. (A real world must exist, although it seems unlikely that the human mind can comprehend reality.) On the other hand, dualism in its Platonic or Cartesian form is difficult to justify, for body and mind are obviously intimately related. And how can two things which are entirely distinct possibly affect each other?

The only practical way out of this dilemma seems to lie in adopting a monistic conception of the body-mind relationship—in conceiving of body and mind as different aspects of one reality, like form and substance, energy and matter, which we shall never fully understand. Do we not see drugs, diseases, operations on the brain, exerting a profound effect on the mind? Alteration of the body leads to alteration of the mind. That is certain, and there is also evidence, I think, that alteration of the mind due to emotional shock, long imprisonment, religious conversion, mystical experience, mental disease, and even application of the mind to a profession, may have some direct effect on the structure and functions of the body, although less quickly, to a less extent, and less consistently. We must picture body and mind developing together from birth and being maintained together throughout life, the one reacting back upon the other. Such, as I see it, is the psychosomatic nature of mankind.

We cannot, however, escape from the common conception of the dualism of our nature engendered by personal conviction based on individual experience of the freedom of the human will. "All theory and evidence is against the freedom of the will," said Dr Johnson, "all experience for it." Now I do not propose to argue for or against the existence of the freedom of the human will, or to discuss the nature of something in ourselves which gives us the feeling of being able to control, within limits, our own thoughts and actions. Still less shall I attempt to define the level where freedom ends and determinism begins. I am concerned with a practical problem, endeavouring to outline a working conception of medicine in our present state of knowledge. Now it is easy to argue against free will, and when I stop to think I may begin to doubt that I possess it. But I do know that I live my life as if I did. I also know that other people live their lives as if they did. Therefore, I cannot leave free will out of my picture of disease which must involve a concept of the mind.

The brain is certainly the product, like any other part of the body, of the genetic plan and the environment in which it develops. It would therefore seem reasonable to me to suppose that the brain permits the development of consciousness, and that its physical characteristics

* The first Croonian lecture for 1950 delivered before the Royal College of Physicians of London on May 9. The second lecture will appear in a forthcoming issue.

Association of Clinical Pathologists

The next meeting of this association will be held on Jan 25, 26, and 27, 1951, at the Westminster Hospital, London

Royal Society of Arts

On Wednesday, Nov 29, at 2.30 p.m., Lord Horder will give a lecture to this society at their house in John Adam Street, London, WC 2, on Cities without Noise

Modern Methods of Diagnosis and Treatment

A series of postgraduate lectures with this general title is to be given at the hall of the Society of Apothecaries from Dec 4 to 8. Further particulars will be found in our advertisement columns

Christian Medical Fellowship

On Tuesday, Nov 28, at 8.15 p.m., at the house of the Royal Empire Society, Craven Street, London, WC 2, Mr H. J. Seddon will speak on the Christian Heritage in Medicine

Aberdeen University Club in London

This club is holding a dinner and dance on Thursday, Dec 14, at the Hyde Park Hotel, Knightsbridge, SW 1 at 7.30 p.m. Tickets (25s) may be had from Dr Henderson, the secretary of the club, Southern Hospital, Dartford, Kent, before Dec 11

Giba Foundation Lecture

Sir Stanton Hicks, professor of human physiology and pharmacology in the University of Adelaide, will deliver a lecture at the foundation, 41, Portland Place, London, W 1 on Tuesday, Dec 12, at 5 p.m. He is to speak on the Role of Suprarenal Cortical Function in Disorders of Childhood

Accidents in the Home

This subject will be discussed at a meeting to be held in the Town Hall, Salford, at 2.30 p.m., on Wednesday, Nov 29. The opening speakers are to be Dr C. A. Boucher, of the Ministry of Health, London, and Mrs Winifred Duncan, home safety department of the Royal Society for the Prevention of Accidents, London

Manx Crisis

According to press reports, the 34 Manx chemists who as we reported last week have withdrawn from the health service have intimated their willingness to resume work at once if the Health Service Board will give them three months notice, from Oct 1, of its intention to impose a charge on prescriptions and containers

Christmas Seals

The Canadian Tuberculosis Association have given the National Association for the Prevention of Tuberculosis 50 million seals to sell in aid of their funds. The seals cost 4s for 100 and may be obtained from the N.A.P.T., Tavistock House North, London, WC 1. Christmas cards (6d each) and whist score cards (10s per 100) are also for sale

"Closed Shop" in Durham

As mentioned in our parliamentary columns, Durham County Council has decided to dismiss any of its employees who do not belong to a trade union or professional association. The 50 odd doctors who are involved are reported to have decided to ignore this ruling which is to be discussed again at a special meeting of the council on Nov 28

Scientists Talking

Sir Leonard Parsons, F.R.S., Prof A. P. Thomson, and Prof S. Zuckerman, F.R.S. are to be among the members of the new Lunar Society of the Air whose unscripted after dinner conversation on subjects of "public interest and real scientific significance" is to be broadcast on the Midland region of the BBC (278 m). The original Lunar Society, which met in Birmingham in the 18th century, included Dr Erasmus Darwin amongst its members. The first meeting of the new series will be broadcast this evening, Nov 24 at 10 p.m., when the Effects of Medical Progress will be the subject of the discussion. Later subjects will include Pressure of Population on World Resources, Telepathy and the Future Evolution of Man

On Nov 15, Sir James Learmonth was invested with the insignia of a chevalier of the League of Honour

THE PATIENT AND HIS DISEASE *

A E CLARK-KENNEDY

M.D. Camb., F.R.C.P.

PHYSICIAN TO THE LONDON HOSPITAL AND DEAN OF THE
MEDICAL SCHOOL, FELLOW OF CORPUS CHRISTI COLLEGE,
CAMBRIDGE

I HAVE not made any particular contribution to medicine which I can now take the opportunity to expound as Dr William Croone would have wished I, therefore propose, although I fully realise how ill qualified I am to make the attempt, to paint in these two lectures a picture of medicine as a single undivided whole. That I shall appear superficial is inevitable, too theoretical for your liking probable I shall be tedious, telling you nothing new, merely gathering up the strands and tying together the loose ends of our existing knowledge. But I am so convinced of the need for a general concept on which we can to some extent agree that I am impelled to try. Without it, we run a grave risk of losing touch with one another. Moreover, our vision of the whole is tending to be obscured more and more by the increasing amount of technical knowledge which we must each acquire.

Body and Mind

The ordinary man, student or teacher, doctor or patient, thinks of himself (when he is not attempting to argue metaphysics) as a body and mind, the former as something which he can see and feel, the latter as something intangible and yet as something of which he is absolutely certain. "I think, therefore I am" was the starting point of the Cartesian system of philosophy. But what is body and what is mind? What is the relationship between them? What attitude to these problems should the doctor adopt? These questions must be answered, in so far as they can be answered, I think, at the start.

Science, organised common sense, teaches that the human body is the product of the plan laid at its conception and the environment in which it develops. It is often compared to a machine the design of which is the result of deliberate thought directed towards a certain end. But the design of the human body is the result of mutation and natural selection in the course of organic evolution. A machine must be copied. But the general design of the body is inherited. Machines are turned out to a standard pattern. Bodies differ slightly, their individual details being largely determined by the chance mating of two people of opposite sex, and then, according to genetic theory, by the chance union of two gametes and the reshuffling of the genes. The execution of a plan for a machine depends on deliberate action. The plan for a human body executes itself. A machine has to be actively maintained. A human body, kept supplied with the necessary materials, maintains its characteristic form and function, as predestined in the plan whence it was derived, and continues to convert chemical energy into heat and the kinetic energy of movement. In fact the human machine differs fundamentally from the machines of man's invention. It is alive, self-developing and self-maintaining, self-repairing and self-reproducing. Moreover, it maintains a system of high energy content in a world in which the general tendency is in the direction of the dissipation of energy. It permits the development and maintenance of consciousness and mind.

Consciousness appears to depend in some way on the brain which is part of the body. The development of

the mind under the stimulus of experience seems to be conditioned by the physiological characteristics of the brain. (The individual mind, therefore, like the individual body, depends to some extent on chance.) According to one view consciousness and mind are both epiphenomena of matter. The brain is said to make consciousness, in much the same sense that the heart circulates the blood, and the reactions of the mind are said to be determined, by physicochemical changes in the brain. But if all human behaviour was determined by conditioned reflexes, consciousness, which allows of pain and pleasure, and permits the development of the conscious mind which asks the question, would still remain mysterious. Materialism leaves the "I think, therefore I am," the certainty of self, entirely unexplained. Moreover 20th-century physics has reduced the extension of concrete objects in space and time to conceptions of the mind, while modern physiology compels the conclusion that their sensory qualities, which we unthinkingly attribute to them in their own right, are really added by the human nervous system. Idealism, however, is unsatisfactory. It conceives that all physical events take place in mind, which is contrary to common sense. (A real world must exist, although it seems unlikely that the human mind can comprehend reality.) On the other hand, dualism in its Platonic or Cartesian form is difficult to justify, for body and mind are obviously intimately related. And how can two things which are entirely distinct possibly affect each other?

The only practical way out of this dilemma seems to lie in adopting a monistic conception of the body-mind relationship—in conceiving of body and mind as different aspects of one reality, like form and substance, energy and matter, which we shall never fully understand. Do we not see drugs, diseases, operations on the brain, exerting a profound effect on the mind? Alteration of the body leads to alteration of the mind. That is certain, and there is also evidence, I think, that alteration of the mind due to emotional shock, long imprisonment, religious conversion, mystical experience, mental disease, and even application of the mind to a profession, may have some *direct* effect on the structure and functions of the body, although less quickly, to a less extent, and less consistently. We must picture body and mind developing together from birth and being maintained together throughout life, the one reacting back upon the other. Such, as I see it, is the psychosomatic nature of mankind.

We cannot, however, escape from the common conception of the dualism of our nature engendered by personal conviction based on individual experience of the freedom of the human will. "All theory and evidence is against the freedom of the will," said Dr Johnson, "all experience for it." Now I do not propose to argue for or against the existence of the freedom of the human will, or to discuss the nature of something in ourselves which gives us the feeling of being able to control, within limits, our own thoughts and actions. Still less shall I attempt to define the level where freedom ends and determinism begins. I am concerned with a practical problem, endeavouring to outline a working conception of medicine in our present state of knowledge. Now it is easy to argue against free will, and when I stop to think I may begin to doubt that I possess it. But I do know that I live my life as if I did. I also know that other people live their lives as if they did. Therefore, I cannot leave free will out of my picture of disease which must involve a concept of the mind.

The brain is certainly the product, like any other part of the body, of the genetic plan and the environment in which it develops. It would therefore seem reasonable to me to suppose that the brain permits the development of consciousness, and that its physical characteristics

* The first Croonian lecture for 1950 delivered before the Royal College of Physicians of London on May 9. The second lecture will appear in a forthcoming issue.

condition the way in which the mind develops under the stimulus of education and experience. It would also appear to me that the mind so developed can influence to some extent the further development and subsequent maintenance of the body. But in our present state of knowledge I do not think that we are justified in assuming that the mind can be explained entirely in terms of the structure of the brain, which the individual inherits, and the experience through which he passes—in spite of the success of modern clinical psychology. Something in our make up seems to allow us to force ourselves to some extent against the tides which tend to influence our thoughts and actions, and enables us to appreciate moral and æsthetic values which science is unable to take into account and which empirical psychology does not even attempt to explain. Nevertheless, this dichotomy must be at a higher level than Plato or Descartes supposed. At the lower level of the mind which is the legitimate field of medical practice, body and mind are intimately related. In fact the Aristotelean conception of body and mind (Aristotle called it soul) intimately compounded, with the understanding or reason which asks the question and attempts the answer as something distinct, is a more satisfactory working hypothesis. True that it was part of the scientific system which dominated the Middle Ages and which Descartes set out to destroy. But it fits in better with our clinical experience today!

Variation, Constitution, and Disease

In health, as popularly conceived, a man, as thus in part we understand him—the product of his heredity, his experience and the use which he makes of his mind—is usually more or less unaware of the internal environment of his body. Moreover, the working of his internal machinery has no effect on consciousness until the limit of the capacity of one of his functions is reached. Then he does experience symptoms. Now in the literal sense of the word he is diseased. Similarly, except when his attention is concentrated on some particular object, he is only vaguely aware of his external environment, unless it changes suddenly. Given time, the functions of his body usually keep his internal environment constant. He can develop his muscles and increase his vital capacity a little, and by improving his coordination of movement increase the efficiency of his physical machine, but fatigue prevents him exerting himself to the point at which he would develop severe acidosis, and respiratory distress from overtaking his heart as the result of running "all out" at the end of a race. On the other hand, the body can adapt itself to continuous demand on function from within, as in the modification of structure which brings the economy of the pregnant woman into line with that of her developing child, and enables the heart to meet the additional load thrown on it when the peripheral resistance to the flow of blood increases. It is also capable of adaption to some extent to a new environment, as in life at high altitudes, residence in the tropics, and employment in a new occupation. In fact the human body is a coordinated, balanced, self-regulating machine, in equilibrium with demand on function from within and (up to a certain point) in equilibrium with its changing environment without.

But extensive variation is inevitable. The chance of even two members of the same family (identical twins excepted) being derived from similar genetic plans must be remote. Environment varies with race and creed, social circumstances, and economic conditions, class and cultural tradition often determining diet, exercise and recreation, and the outlook of the developing mind. Besides, men elect to live their lives differently, meet with good or bad luck, and endeavour to modify their environment to suit their individual taste. Every man, therefore, develops a constitution peculiarly his own,

the product of his genetic origin and his life in his environment. It evolves quickly in childhood as the plan whence he is derived takes shape, and in adult life it may seem fairly set. But throughout life each new experience, physical or mental, plays some part in determining the reactions of his body or his mind to experience still to be encountered.

Thus a man may grow up vigorous or lethargic, easily tired or capable of sustained exertion, placid or emotional, musical or mathematical. His character is often reflected in his face and his state of mind in his expression. His philosophy of life, it would appear, is to a large extent determined by what heredity and environment dictate. One is somatically strong, his body can cope with considerable demand on function and he is adaptable to change of environment, and resistant to infection. But he is psychologically weak, his mind cannot stand up to intellectual demand or emotional strain. Another is somatically weak, more liable than other people to succumb to demand on physical function. But he is psychologically strong, emotionally stable and capable of sustained mental effort. A third is somatically weak and psychologically weak. He cannot stand up either to physical or to mental strain. His mind may be peculiarly sensitive to his body, so that a slight disturbance of physical health leads to depression unjustified by circumstances, or his body to his mind so that a slight emotional upset leads to over stimulation of his sympathetic nervous system. A man of this type is bound to make "heavy weather" of any environment which this world is likely to provide.

Some of the features of a man's constitution, as thus I conceive it, appear to be genetic. His sex and blood group are certainly genetic, and the study of his family often suggests that the main peculiarities of his body and the outstanding characteristics of his mind are largely genetic. Others seem to be due mainly to the action of the environment in which he is compelled to live or to the way in which he has chosen to live, for instance, his complexion, muscular development, and mental reactions, as a study of his life history reveals. But it is very easy to make a mistake. The plan whence every individual is derived is hidden, and "inheritance" of environment is very easily confused with true heredity. Further, the distinction between the action of the genes and the influence of environment is far less clear now than was once supposed, and, for all we know, the specific force of the genes may be profoundly influenced by the conditions under which they act. Genetic factors determine the way and extent to which the developing body responds to the influence of environment. Two genetic plans in different environments can produce two individuals surprisingly alike. Conversely, different environments can mould two genetic plans into similar shape. In fact it seems reasonable to suppose that there are few bodily features commonly attributed to heredity which cannot also be produced mainly by environment, and few usually attributed to environment which cannot also sometimes be explained in terms of heredity. The relative importance of genetic and environmental factors is exceedingly difficult to assess in any attempt to analyse the constitution of a man.

The same difficulty arises in any attempt to analyse the causes of disease. For disease, as we understand it, must be due to genetic faults, adverse factors in environment, or the way in which a man uses his mind, or to some combination of these three factors, interfering still further with the normal balance of human bodies or minds. (In the present state of our knowledge we cannot conceive of it being produced in any other way.) The body may fail to develop or maintain itself properly as a result of a serious fault in its genetic plan. It may succumb to mischance in its environment. The mind

may suffer in consequence of genetic or acquired disease of the body, or succumb to adverse factors influencing it direct through the understanding. Diseases of the mind, in so far as the mind can be separated from the body, may interfere with the structure and functions of the body. Moreover, a deliberate act of will may run the body into one of the risks in the environment against which it is unprotected but which it would have otherwise avoided. Lack of mental effort may result in a man failing to rise superior to circumstances from which there is no hope of physical escape.

The Pathology of the Body

In pursuing this conception further, let us start with the maternal risks to which the body, divorced as far as possible from the influence of the mind, as we understand it, may from time to time succumb, in fact with the maternal risks which lead to structural changes that can be studied, at least to some extent, in the body after death. These can be divided, in so far as it is justifiable to distinguish between heredity and environment (it is necessary to force this distinction to some extent in any attempt to analyse the causes of disease) into three groups. Let us consider them in turn.

1 There may be a fault in the genetic plan whence the individual is derived, with the result that his bodily machinery is not properly balanced from the start, or his brain will not permit the development of a normal mind. But life really starts at conception, and it is difficult in practice to distinguish between disease which is truly genetic and congenital disease which has been acquired in utero. Nevertheless to confine our conception of genetic factors in the pathogenic disease to conditions transmitted according to Mendelian laws is to take too limited a view of their influence. Genetic factors probably play a part in the pathogenesis of many other conditions, and on general grounds it seems reasonable to suppose that they must often be largely responsible for constitutional weakness of body and mind of sufficient severity to be dignified with the title of disease. It is also probably true that many cases of congenital malformation of structure and abnormality of function, for which no environmental cause can be discovered, are genetic, although their true nature cannot be proved because the plan whence the individual is derived is hidden from our sight.

2 The body may succumb to one of the many risks to which it is exposed in its environment during antenatal and postnatal life. These fall into four main groups. First, it may be damaged by physical forces. These include heat, light, X rays (which lead also to aplasia of the bone marrow and are known to cause mutation of the germ plasma leading to genetic disease in subsequent generations), and trauma. The risk of mechanical injury before birth is negligible, at birth considerable. After birth it is variable, depending on individual way of life and occupation. For the body may now be caught unawares by forces against which reflex action is inadequate to protect it, damaged by internal stress which it is constitutionally not strong enough to withstand, or overtaken by danger from which the conscious reactions of the mind and the functions of the body working to full capacity do not permit it to escape. The second great risk in this class is malnutrition. The body may be deprived for one reason or another of one or more of those substances on which its development and maintenance depend. The supply of oxygen may fail. It may run short of water, salt, calories, protein, vitamins, or minerals. The third risk is poisoning by substances used in medical practice and industry or taken for pleasure. The fourth and perhaps the greatest, is infection. Before birth syphilis of the placenta may lead to abortion, stillbirth, or the congenital disease, and

viruses passing through it in the early months of pregnancy are known to cause foetal malformation. After birth the body is exposed to invasion by pathogenic organisms and parasites, and may suddenly encounter a type of organism against which it is completely unprotected and to which it inevitably succumbs.

3 Distinct from these two main classes of risk there is however, a third, encountered only under the peculiar circumstances which obtain during antenatal development. A constitutional factor in the child, genetically determined according to Mendelian laws and antigenic to the constitution of its mother determined by the same laws, may lead to modification of her internal environment, and therefore of the external environment of her child. Under these circumstances, if Rh antigen and antibody can both pass freely across the placental boundary, antigen antibody reactions in the child in the later months of pregnancy may lead to antenatal death, severe anaemia at birth, or a defect in the development of the brain predisposing to failure of mental development after birth. This risk—and there may be others of a similar kind still to be discovered—links disease due to faults in the genetic plan with disease due to adverse factors in environment.

The risks to which we are exposed are great. In fact a man would not long survive his birth did he not inherit the potential power of reacting not only in such a way as to avoid most of the dangers to which he is constantly exposed, but also, when these reactions fail, in such a way as to conserve his structure and functions and (unless adverse factors act too strongly) maintain his existence as a unit of life and mind although at a lower level of efficiency. Action on the body may interfere with growth, stimulate or depress function, destroy structure, undermine nutrition, or upset endocrine balance. But the body is a balanced system, and action on the body almost always leads to reaction by the body. Thus mechanical injury of all kinds leads to proliferation of tissue, which organises clot, closes wounds, and unites fractured bones. Chemical poisons are eliminated by the lungs or kidneys, detoxicated in the liver or tissues, or stored in the bones. Acute infection stimulates inflammation, fever, and immunity, chronic infection leads gradually to fibrosis. But these reactions are not always advantageous to us, and sometimes man has to pay a price for this power with which every human body is endowed. Reactionary fibrosis often leads to pressure or mechanical obstruction. The innate capacity of the body to respond to antigens by the production of antibodies on which immunity depends is also responsible for Rh reactions in infants and many incompatible blood transfusions in adults, and often results in allergic reactions which may modify adversely the subsequent course of infection in the human body.

These actions on, and these corresponding inborn reactions by, the body are the primary pathological processes of the body. Thinking of them from the point of view of their cause, some appear to be genetic. Others seem to be acquired during life in the environment. Both can be congenital. Sometimes a genetic defect transmitted according to Mendelian laws acts alone to alter structure and disturb function. For instance, the meeting of two recessive genes of a certain type when the plan is laid leads to deafness when the child is born. No adverse factor in environment can be held responsible for the condition, and we can be certain that the cause of it lay wholly in the plan whence the individual was derived. At other times the cause of a disease seems to lie wholly in environment. When a normal man is damaged in an accident, is poisoned, or succumbs to some virulent infection to which he is unluckily exposed, it is difficult to blame his genetic origin. His disease can be attributed entirely to mischance and to a pathological process of an

condition the way in which the mind develops under the stimulus of education and experience. It would also appear to me that the mind so developed can influence to some extent the further development and subsequent maintenance of the body. But in our present state of knowledge I do not think that we are justified in assuming that the mind can be explained entirely in terms of the structure of the brain, which the individual inherits, and the experience through which he passes—in spite of the success of modern clinical psychology. Something in our make up seems to allow us to force ourselves to some extent against the tides which tend to influence our thoughts and actions, and enables us to appreciate moral and æsthetic values which science is unable to take into account and which empirical psychology does not even attempt to explain. Nevertheless, this dichotomy must be at a higher level than Plato or Descartes supposed. At the lower level of the mind which is the legitimate field of medical practice, body and mind are intimately related. In fact the Aristotelian conception of body and mind (Aristotle called it soul) intimately compounded, with the understanding or reason which asks the question and attempts the answer as something distinct, is a more satisfactory working hypothesis. True that it was part of the scientific system which dominated the Middle Ages and which Descartes set out to destroy. But it fits in better with our clinical experience today.

Variation, Constitution, and Disease

In health, as popularly conceived, a man, as thus in part we understand him—the product of his heredity, his experience and the use which he makes of his mind—is usually more or less unaware of the internal environment of his body. Moreover, the working of his internal machinery has no effect on consciousness until the limit of the capacity of one of his functions is reached. Then he does experience symptoms. Now in the literal sense of the word he is diseased. Similarly, except when his attention is concentrated on some particular object, he is only vaguely aware of his external environment, unless it changes suddenly. Given time, the functions of his body usually keep his internal environment constant. He can develop his muscles and increase his vital capacity a little, and by improving his coördination of movement increase the efficiency of his physical machine, but fatigue prevents him exerting himself to the point at which he would develop severe acidosis, and respiratory distress from overtaxing his heart as the result of running “all out” at the end of a race. On the other hand, the body can adapt itself to continuous demand on function from within, as in the modification of structure which brings the economy of the pregnant woman into line with that of her developing child, and enables the heart to meet the additional load thrown on it when the peripheral resistance to the flow of blood increases. It is also capable of adaption to some extent to a new environment, as in life at high altitudes, residence in the tropics, and employment in a new occupation. In fact the human body is a coördinated, balanced, self-regulating machine, in equilibrium with demand on function from within and (up to a certain point) in equilibrium with its changing environment without.

But extensive variation is inevitable. The chance of even two members of the same family (identical twins excepted) being derived from similar genetic plans must be remote. Environment varies with race and creed, social circumstances, and economic conditions, class and cultural tradition often determining diet, exercise and recreation, and the outlook of the developing mind. Besides, men elect to live their lives differently, meet with good or bad luck, and endeavour to modify their environment to suit their individual taste. Every man, therefore, develops a constitution peculiarly his own,

the product of his genetic origin and his life in his environment. It evolves quickly in childhood as the plan whence he is derived takes shape, and in adult life it may seem fairly set. But throughout life each new experience, physical or mental, plays some part in determining the reactions of his body or his mind to experience still to be encountered.

Thus a man may grow up vigorous or lethargic, easily tired or capable of sustained exertion, placid or emotional, musical or mathematical. His character is often reflected in his face and his state of mind in his expression. His philosophy of life, it would appear, is to a large extent determined by what heredity and environment dictate. One is somatically strong, his body can cope with considerable demand on function and he is adaptable to change of environment, and resistant to infection. But he is psychologically weak, his mind cannot stand up to intellectual demand or emotional strain. Another is somatically weak, more liable than other people to succumb to demand on physical function. But he is psychologically strong, emotionally stable and capable of sustained mental effort. A third is somatically weak and psychologically weak. He cannot stand up either to physical or to mental strain. His mind may be peculiarly sensitive to his body, so that a slight disturbance of physical health leads to depression unjustified by circumstances, or his body to his mind so that a slight emotional upset leads to over stimulation of his sympathetic nervous system. A man of this type is bound to make “heavy weather” of any environment which this world is likely to provide.

Some of the features of a man's constitution, as thus I conceive it, appear to be genetic. His sex and blood group are certainly genetic, and the study of his family often suggests that the main peculiarities of his body and the outstanding characteristics of his mind are largely genetic. Others seem to be due mainly to the action of the environment in which he is compelled to live or to the way in which he has chosen to live, for instance, his complexion, muscular development, and mental reactions, as a study of his life history reveals. But it is very easy to make a mistake. The plan whence every individual is derived is hidden, and “inheritance” of environment is very easily confused with true heredity. Further, the distinction between the action of the genes and the influence of environment is far less clear now than was once supposed, and, for all we know, the specific force of the genes may be profoundly influenced by the conditions under which they act. Genetic factors determine the way and extent to which the developing body responds to the influence of environment. Two genetic plans in different environments can produce two individuals surprisingly alike. Conversely, different environments can mould two genetic plans into similar shape. In fact it seems reasonable to suppose that there are few bodily features commonly attributed to heredity which cannot also be produced mainly by environment, and few usually attributed to environment which cannot also sometimes be explained in terms of heredity. The relative importance of genetic and environmental factors is exceedingly difficult to assess in any attempt to analyse the constitution of a man.

The same difficulty arises in any attempt to analyse the causes of disease. For disease, as we understand it, must be due to genetic faults, adverse factors in environment, or the way in which a man uses his mind, or to some combination of these three factors, interfering still further with the normal balance of human bodies or minds. (In the present state of our knowledge we cannot conceive of it being produced in any other way.) The body may fail to develop or maintain itself properly as a result of a serious fault in its genetic plan. It may succumb to mischance in its environment. The mind

lesion in the cerebrum leads to uncontrolled activity of the lower centres in the pons, it may stimulate growth or function out of proportion to the needs of the body as a whole or interfere with the balance of the endocrine system on which structure and function both depend. But action on the body tends to reaction by the body. Some of these reactions tend to defeat or aggravate adverse action on it, as in the production of antibody in response to antigen in immunity and allergy respectively. Others lead to hypertrophy of some other structure and compensatory overaction, or to atrophy or reduction of the activity of some other function, maintaining integration of structure and function and conserving the body for the time being, although at a lower level of efficiency, as a unit of life and of potential or developed mind. Thus the course and final outcome of a disease process depends on the relative intensity and speed of adverse action on the body in relation to the rate at which, and the efficiency with which, the body reacts. A sudden attack may overwhelm it when ill prepared or undefended, but adverse factors which act slowly do not lead to failure of function until the process of adaptation has reached its limits or for some other reason compensation suddenly breaks down.

Nevertheless the distinction between action and reaction by the body, like most of the distinctions which the human mind imposes on nature, cannot always be maintained. "Action on" often merges imperceptibly into "reaction by" the body, the alterations of structure and disturbances of function produced appearing as a complicated pattern of relationships dominated (at least so it looks to us) by the body "struggling" under adverse circumstances "purposely" to keep itself alive. Indeed it is difficult to contemplate the picture painted by disease without doubting the purely mechanical conception of causation. Hume's challenge has never really been answered, and the modern mathematical conception of the physical universe throws grave doubt upon the validity of the principle of mechanical causation. Moreover, philosophical thought is tending to regard the universe as a progressive process which the human mind, as Kant maintained, carves up to fit in with its preconceived ideas of law, order, and causation. One day we may revert to the Aristotelian conception that the cause lies to some extent in the end and not only in the events which come before it.

When the patient dies, functional activity is suddenly arrested. Structural changes thus far produced—those due to action on and those due to reaction by the body—can be spread out to view on the post mortem table and seen for a brief period in relation to each other, as they were when the individual life was finally defeated. They often throw light on the mechanism of death. Sometimes the cause of it can actually be demonstrated. More often the post mortem reveals it within the generally accepted sense, only because the structural changes revealed are typical, in appearance and distribution, of a known action on the body. More often still there are no visible changes due to action on the body, and the diagnosis depends on the reactions by the body and the structural consequences of progressive failure of function. But in a short illness there is little time for structural change due to reaction by the body or for structural change due to progressive failure of function, and under these circumstances, unless the post mortem reveals a sudden catastrophe, such as a fatal pulmonary embolus or an extensive cardiac infarct, it may fail to provide a complete explanation of the mechanism of death. Even in some chronic conditions—untreated diabetes and idiopathic steatorrhœa for instance—little structural change due to its primary cause can ever be demonstrated on the post mortem table. The post mortem method has its limitations, particularly in acute cases. No characteristic changes in the structure of the heart ever prove

that death was due to ventricular fibrillation or status epilepticus. A functional conception of disease is necessary for that. No functional conception explains death due to hydrocyanic acid poisoning or many cases of acute infection. The basic chemical conception of disease which I have endeavoured to outline must now be invoked. But not even that will explain why a man "blew out his brains," on which his mind was based, or flung into the water the body to which his brain belonged. The pathology of the mind which deliberately drank the corrosive, swallowed the veronal tablets, or turned on the gas unlighted, calls for an explanation which examination of the dead body is unlikely ever to provide.

The Pathology of the Mind

The brain is well developed by full term. During fetal life, however, the oxygen pressure in the arterial blood is too low to permit the development of consciousness and mind. Consciousness can only start at birth. Mind can only develop gradually under the stimulus of experience, a process which is difficult to study and which can only be described empirically in terms of attributes transmitted from one generation to the next and determined by the structure of the human brain. Subjective sensations of pleasure and pain presumably come first. Then satisfaction and frustration of instinct stimulate emotional feeling—so at least we must suppose—experience being stored in memory permitting the association of past events and rendering a conception of the future possible. As time passes, reason under the stimulus of observation and experience, and later under the stimulus of education, discovers that certain principles, once grasped from a few examples, are self-evident in the sense that they never stand in need of further proof. Thus individually we began to understand the world. Thus collectively we have arrived at empirical and a-priori knowledge. But the intellect can develop only within the limits set by the functional efficiency of the cerebral machinery, the third-class differing from the first-class mind, we must suppose, because of physicochemical differences in the underlying brain. "Two glasses can be equally full," said Dr Johnson, "but one holds more water."

Normally the brain permits the development under the stimulus of experience, and the subsequent maintenance, of a mind of average intellectual ability and sufficiently robust to weather the mental stresses and emotional storms of an average life. But it is always bound to give way if at any time a pathological process of the body interferes sufficiently with the structure of the brain or with any function of the body on which the brain depends. A head injury may lead to permanent mental defect. Deficiency of vitamin B is associated with characteristic mental failure. Arterial anoxæmia due to low oxygen pressure in the atmosphere or to advanced disease of heart or lungs may lead to complete confusion. Chemical poisons, alcohol, morphine, and cocaine cause mental deterioration. Acute infections may lead to delirium, chronic infections to mental changes depending in part on the nature of the infection and in part on the personality of the patient. Progressive failure of the cerebral circulation due to the degenerative changes of advancing age often leads to exaggeration of individual characteristics, sometimes to reversal of character, occasionally to complete alteration of personality. But in all these conditions the mind is not primarily affected. If the body recovers, the mind recovers, provided no permanent damage has been done.

Sometimes, however, the development of the brain does not permit the development of a normal mind. In some children a defect in the genetic plan or adverse factors in intra uterine environment lead to mental deficiency. In others intellectual development proceeds normally but the brain so conditions the development of

acquired kind. But in most conditions environment is merely revealing an innate predisposition, and the view held as to the causation of many diseases is likely to depend very largely on the standpoint of the particular observer. Thus a doctor seeing a tendency to scurvy or tuberculosis in a family in his practice among a population living on a poor diet may well think in terms of genetic weakness. The public health officer, on the other hand, with access to statistics and surveying the scene as a whole, is more likely to attribute the increasing incidence of the disease mainly to environment. Hence, I think, the concentration on heredity diathesis in the 18th and on environmental factors with the deterioration of the standard of living and the growth of the public health services in the 19th century. In the 20th century we ought to be able to take a more balanced view. Genetic and environmental factors interact in the pathogenesis of most clinical conditions. Even hæmophilia remains unsuspected until some trivial injury precipitates bleeding, and colour blindness often passes unrecognised unless it leads to some disaster. Proneness to commit misjudgments predisposing to accidents may be to some extent genetic, and there is evidence that peculiar liability to vitamin deficiency, idiosyncrasy to chemical substances, and particularly susceptibility to infection are often genetic. The association of increasing maternal parity with the occurrence of certain congenital conditions in uniovular twins, more commonly than can be explained in terms of probability, suggests that they are the product of genetic and intra uterine factors. Statistical evidence points to a genetic predisposition to many of the disorders of later life, and the common occurrence of a disease more frequently in one sex than in the other suggests a partially sex limited genetic factor in its pathogenesis, although some adverse factor in environment must lead the individual to succumb. Many diseases are probably due to the chance combination of a peculiar genetic weakness with a particular environmental defect.

Trauma, malnutrition, chemical poisoning, and infection (although no absolute distinction can be drawn between them), and the corresponding reactions by the body, stand out as pathological processes which we can claim, at least to some extent, to understand. New growth, the degenerative changes of advancing age, and a number of other recurring structural changes in the human body still remain mysterious. How are we to think of them from this point of view in our present state of knowledge?

The growth of all living things depends on heredity and environment, and new growth seems likely to be due to mutation or to some permanent alteration of the environment of certain cells. The discovery that some types of malignant growth can be started in animals by the application of chemical substances, and then transmitted indefinitely by implantation, certainly suggests that naturally occurring cancer may be due to the production (or failure of production) of some chemical substances within the body as the result of trauma, infection, or degeneration, changing the genetic constitution of certain cells, altering their growth behaviour. The transmission of other types by the injection of cell free extracts suggests that they may be due, in part at least, to a virus gaining access to certain cells and then being transmitted at each cell division, with the result that all successive generations inherit the same environment. Further than that we cannot go at present.

Wear and tear must play some part in the pathogenesis of the degenerative processes of advancing age, but the frequent death of identical twins from arteriosclerotic causes at the same period of life suggests that genetic factors must be more important than is generally supposed. Genetic make-up predisposes to acquired conditions, and one acquired pathological process predisposes

to another—trauma to infection, infection to malnutrition, and malnutrition to infection.

Bearing all the facts in mind it seems reasonable to suppose that all structural changes met with in the body—new growth, degeneration, and the rest—are potentially capable of explanation in terms of variation on the same major theme. They depend in fact on complicated reactions at different ages between genetic constitution and the functional disturbances (including allergy and disturbance of endocrine balance) produced by different combinations of four acquired pathological processes corresponding to the four great risks to which we are exposed (it is difficult to conceive of any others)—namely, trauma, malnutrition, chemical poisoning, and infection.

What is the basic nature of these four processes? If we take them one by one we shall see that they must be chemical. The genes are said to be non repetitive crystalline molecules which in some way transform the chemical nature of substances derived from the environment and arrange them in a pattern giving rise to the characteristic architecture and the regular reactions which underlie the functions of the human body. A pathological process of genetic origin, therefore, must be chemical. Pathological processes due to lack of the substances on which the maintenance of nutrition depends are obviously chemical. Mechanical injury, heat, cold, and radiation are forms of physical action, but no fundamental distinction between chemical and physical action can be maintained. Poisons exert their action chemically, some by destroying living tissue by oxidation or the coagulation of protein on which the structure of living cells depends, others by exerting a specific action on some function of the body. Pathogenic organisms affect the body by secreting substances which exert a specific action on certain tissues, by competing for the substances on which its life depends, by producing substrates out of which its enzymes produce useless metabolites, or by stimulating allergic reactions. Infective disease must depend on interaction between the chemical way of life of parasite and human host. All organic pathological processes, therefore, are essentially of physicochemical nature, chemical action on, and chemical reaction by, the body tending to alter the static chemical arrangements which determine its structure or to disturb the dynamic reactions on which its functional attributes depend. A pathological process is a chemical modification of the body.

A chemical concept of a pathological process is necessary before we can claim to understand it completely. But in practice it is usually sufficient to think in terms of the structural changes and functional disturbances in which chemical changes are reflected. And we must remember that our distinction between structure and function is artificial. (It is our minds which force structure and function apart and technical considerations which compel us to teach them separately.) Function is changing structure, and structure is static function. Both depend on the physicochemical nature of the body. The former on the labile reactions and the latter on the static reactions of the body. Structure and function cannot really be divorced. Functional change leads to structural consequences, as in the hypertrophied heart of hypertension and the anasarca of heart failure. Structural change leads to functional consequences, as in the heart failure of rheumatic carditis and the vomiting of pyloric obstruction. Let us, therefore, leave chemistry behind and proceed to think instead of pathological process in terms of alteration of structure and disturbance of function which can be observed directly.

Action on the body may destroy structure or lead to failure of function. It may unmask some more primitive mechanism. For instance when disease of the auricular ventricular bundle reveals idioventricular rhythm, or a

lesion in the cerebrum leads to uncontrolled activity of the lower centres in the pons, it may stimulate growth or function out of proportion to the needs of the body as a whole or interfere with the balance of the endocrine system on which structure and function both depend. But action on the body tends to reaction by the body. Some of these reactions tend to defeat or aggravate adverse action on it, as in the production of antibody in response to antigen in immunity and allergy respectively. Others lead to hypertrophy of some other structure and compensatory overaction, or to atrophy or reduction of the activity of some other function, maintaining integration of structure and function and conserving the body for the time being, although at a lower level of efficiency, as a unit of life and of potential or developed mind. Thus the course and final outcome of a disease process depends on the relative intensity and speed of adverse action on the body in relation to the rate at which, and the efficiency with which, the body reacts. A sudden attack may overwhelm it when ill prepared or undefended, but adverse factors which act slowly do not lead to failure of function until the process of adaptation has reached its limits or for some other reason compensation suddenly breaks down.

Nevertheless the distinction between action and reaction by the body, like most of the distinctions which the human mind imposes on nature, cannot always be maintained. "Action on" often merges imperceptibly into "reaction by" the body, the alterations of structure and disturbances of function produced appearing as a complicated pattern of relationships dominated (at least so it looks to us) by the body "struggling" under adverse circumstances "purposely" to keep itself alive. Indeed it is difficult to contemplate the picture painted by disease without doubting the purely mechanical conception of causation. Hume's challenge has never really been answered, and the modern mathematical conception of the physical universe throws grave doubt upon the validity of the principle of mechanical causation. Moreover, philosophical thought is tending to regard the universe as a progressive process which the human mind, as Kant maintained, carves up to fit in with its preconceived ideas of law, order, and causation. One day we may revert to the Aristotelian conception that the cause lies to some extent in the end and not only in the events which come before it.

When the patient dies, functional activity is suddenly arrested. Structural changes thus far produced—those due to action on and those due to reaction by the body—can be spread out to view on the post mortem table and seen for a brief period in relation to each other, as they were when the individual life was finally defeated. They often throw light on the mechanism of death. Sometimes the cause of it can actually be demonstrated. More often the post mortem reveals it within the generally accepted sense, only because the structural changes revealed are typical, in appearance and distribution, of a known action on the body. More often still there are no visible changes due to action on the body, and the diagnosis depends on the reactions by the body and the structural consequences of progressive failure of function. But in a short illness there is little time for structural change due to reaction by the body or for structural change due to progressive failure of function, and under these circumstances, unless the post mortem reveals a sudden catastrophe, such as a fatal pulmonary embolus or an extensive cardiac infarct it may fail to provide a complete explanation of the mechanism of death. Even in some chronic conditions—untreated diabetes and idiopathic steatorrhœa for instance—little structural change due to its primary cause can ever be demonstrated on the post mortem table. The post-mortem method has its limitations, particularly in acute cases. No characteristic changes in the structure of the heart ever prove

that death was due to ventricular fibrillation or status epilepticus. A functional conception of disease is necessary for that. No functional conception explains death due to hydrocyanic acid poisoning or many cases of acute infection. The basic chemical conception of disease which I have endeavoured to outline must now be invoked. But not even that will explain why a man "blew out his brains," on which his mind was based, or flung into the water the body to which his brain belonged. The pathology of the mind which deliberately drank the corrosive, swallowed the veronal tablets, or turned on the gas unlighted, calls for an explanation which examination of the dead body is unlikely ever to provide.

The Pathology of the Mind

The brain is well developed by full term. During foetal life, however, the oxygen pressure in the arterial blood is too low to permit the development of consciousness and mind. Consciousness can only start at birth. Mind can only develop gradually under the stimulus of experience, a process which is difficult to study and which can only be described empirically in terms of attributes transmitted from one generation to the next and determined by the structure of the human brain. Subjective sensations of pleasure and pain presumably come first. Then satisfaction and frustration of instinct stimulate emotional feeling—so at least we must suppose—experience being stored in memory permitting the association of past events and rendering a conception of the future possible. As time passes, reason under the stimulus of observation and experience, and later under the stimulus of education, discovers that certain principles, once grasped from a few examples, are self evident in the sense that they never stand in need of further proof. Thus individually we began to understand the world. Thus collectively we have arrived at empirical and a-priori knowledge. But the intellect can develop only within the limits set by the functional efficiency of the cerebral machinery, the third-class differing from the first-class mind, we must suppose, because of physicochemical differences in the underlying brain. "Two glasses can be equally full," said Dr Johnson, "but one holds more water."

Normally the brain permits the development under the stimulus of experience, and the subsequent maintenance, of a mind of average intellectual ability and sufficiently robust to weather the mental stresses and emotional storms of an average life. But it is always bound to give way if at any time a pathological process of the body interferes sufficiently with the structure of the brain or with any function of the body on which the brain depends. A head injury may lead to permanent mental defect. Deficiency of vitamin B is associated with characteristic mental failure. Arterial anoxæmia due to low oxygen pressure in the atmosphere or to advanced disease of heart or lungs may lead to complete confusion. Chemical poisons alcohol, morphine, and cocaine cause mental deterioration. Acute infections may lead to delirium, chronic infections to mental changes depending in part on the nature of the infection and in part on the personality of the patient. Progressive failure of the cerebral circulation due to the degenerative changes of advancing age often leads to exaggeration of individual characteristics, sometimes to reversal of character, occasionally to complete alteration of personality. But in all these conditions the mind is not primarily affected. If the body recovers, the mind recovers, provided no permanent damage has been done.

Sometimes however, the development of the brain does not permit the development of a normal mind. In some children a defect in the genetic plan or adverse factors in intra uterine environment lead to mental deficiency. In others intellectual development proceeds normally but the brain so conditions the development of

the mind, and the developed mind so conditions the subsequent maintenance of the brain, that the individual has difficulty in standing up to emotional strain during adolescence and is predisposed to mental breakdown in later life under mental stress or in physical ill health. In these cases there is often a family history of mental instability suggesting the transmission of a tendency to mental disease through the structure of the brain. Disease of this kind is also associated, as might be expected, with characteristic physical features, while different types are linked to sex in a way which cannot be explained in terms of predominantly male or female occupations. Moreover, individual cases can seldom be interpreted in terms of psychoanalytical theory, and usually fail to respond to psychotherapy, some form of "shock" directed to the brain being required in their treatment. True, that no organic pathological processes of the body and no histological changes in the brain have ever been demonstrated, but all the evidence points to some structural peculiarity of the cerebrum predisposing to mental breakdown in these patients. No absolute dividing line can be drawn, however, between functional psychoses, due to defects of the brain which as yet have defied analysis at the physicochemical level, and organic psychoses due to recognisable pathological processes of the body.

In other children the somatic constitution of the brain has permitted normal development of intellect and greater emotional stability, but if circumstances are unfavourable they are liable to grow up with a tendency to react abnormally in one way or another to the stresses and strains of adult life. In one, repression of instinct leads to a permanent state of mental tension. In another a capacity to dissociate ideas and respond to suggestion permits subconscious escape from difficult situations or emotional satisfaction in abnormal ways. These conditions are not, as would be expected, associated with any particular characteristic of the body. Nor is there often a definite history of mental instability in the family. Electroencephalograms show no abnormality, and many cases can be explained, in part at least, by psychoanalytical investigation of their mental development. They respond to psychotherapy but are not benefited by empirical treatment directed to the brain. But again no absolute dividing line can be drawn. The psychoneuroses merge imperceptibly into the extreme varieties of normal human personality as generally accepted. Neither is there any exact dividing line between the functional psychoses and the psychoneuroses. Nevertheless it would appear that in the former we should attribute more blame to the physical constitution of the brain and less to abnormal experience, and in the latter less to defect of the brain and more to the experience which on investigation proves to have been unfortunate in early life.

The psychoneuroses are sometimes regarded as pathological processes of the mind, but pathological processes of body and pathological processes of mind differ fundamentally. The former are usually due to abnormal action on, and a normal reaction by, the body, abnormal reaction to normal stimulation, allergy for instance, being on the whole less common. The latter are usually due to normal action on and abnormal reaction by the mind, in other words, abnormal reactions to the kind of stress to which everyone is subjected, mental breakdown entirely due to abnormal experience, true neurasthenia being relatively uncommon except in time of war. Moreover, mind, as man knows it, cannot exist without a functional body, and pathological processes of the mind cannot ever be divorced from the body in the way that pathological process of the body can sometimes be divorced from the mind. This is why I think it is questionable if we can really say that they exist. The health of the body can influence the psychoneurotic just as much

as it can influence the normal reactions of the mind. Therefore, we cannot ever ignore the physical health of the body on which our patient's mind is based.

Freedom of the Will

Disease, as I have said, must be due to faults in the plan whence the individual is derived, to adverse factors in the environment in which he lives, or to the way in which he uses his mind, or, as is often the case, to some combination of these three causes. I have discussed at some length the part played by heredity and environment. Let me now touch on the problem of the use of the mind in relation to disease. For practical medicine must reckon with the apparent freedom of the human will. (Education and the law assume it.) Disease does not always depend on genetic bad luck or environmental mischance. Rather, as we must admit, unless we subscribe to the doctrine of determinism, a deliberate act, some times of the kind universally admired, at other times of the kind held in general contempt, may lead a man to expose his body to trauma, malnutrition, chemical poisoning, or infection from which it would otherwise have escaped. It is even possible that a way of life, good or bad according to generally accepted standards, may accelerate or retard the degenerative processes of advancing age. Moreover, although organic disease undermines the power of the will, does not failure to exercise this power play some part in the genesis of psychoneurotic reactions? Cannot these people make some effort of their own, apart from influence brought to bear upon them, to overcome the handicaps of instinct, environment, and personality, as we all believe we can ourselves in the control of our own lives and the reactions of our more normal minds? But even if we are just machines determined by heredity and past experience, which few really believe, medicine cannot escape the problem of the way in which a man should live and use his mind from whatever source it is derived. The mind is an important factor in the pathogenesis of human disease. We can influence the mind profoundly. Inevitably, therefore, medicine collides head on at times with moral problems.

Some believe in the existence of an objective moral law. Others hold ethical codes to be a product of organic evolution necessary to social living and advantageous to the State, individual moral standards to be subjective judgments determined by environment and past experience. But with this dichotomy in our interpretation of life we are not immediately concerned. For in whatever direction the truth actually lies, the fact remains that most people have some moral sense, be it the result of the repressions of the nursery, the conventions of society, their desire to retain the respect of other people, their religious education, or their own thought out philosophy. A man, therefore, lives in practice, not only in a physical environment of material things and a mental environment of experience affecting him through his understanding, but also in a moral environment, be it the product of his religious education, his own experience, or his a priori intuition of a moral order in the Universe. "Thou shalt love the Lord thy God and Him only shalt thou serve" is the teaching of the Jewish law. "Above all, to thine own self be true" said Polonius in giving fatherly advice to Laertes on the eve of his visit to England. "Act only according to that principle," wrote Kant, "which you can at the same time will to be a universal law."

Medicine is not primarily concerned with moral problems, but when moral sense exists, health and moral judgment may conflict. Action right from the point of view of health may be wrong from the point of view of a patient's moral standards. Then, if he follows medical advice, his mind is sick. Conversely, action wrong from the point of view of health may be right from the point of view of moral standards. Then, if he risks his physical

health, he retains his self respect Under certain circumstances in an individual life there may be no escape from this dilemma At this level of the mind the will, if free to take its choice, must endeavour to escape from the trammels of heredity and the influence of past experience Perhaps this is not possible I do not know Sir, I have reached the limits of our human understanding Let that stop me tonight At the highest level of the mind fools rush in, I sometimes think, where wise men well may fear to tread

ANTICOAGULANT THERAPY WITH HEPARIN IN PITKIN'S MENSTRUUM

J F GOODWIN

M.D Lond., M.R.C.P.

PHYSICIAN AND LECTURER IN MEDICINE, POSTGRADUATE
MEDICAL SCHOOL OF LONDON *

A G MACGREGOR

M.B., B.Sc. Glasg., M.R.C.P., F.R.F.P.S.

LECTURER IN THERAPEUTICS IN THE UNIVERSITY OF SHEFFIELD
SENIOR REGISTRAR ROYAL INFIRMARY, SHEFFIELD

The treatment of thrombo embolic disease with anti coagulants is now widely practised, the choice of drug lying between heparin and the coumarin preparations Heparin is effective and safe, but its use is limited by expense and the difficulty of continuous or frequent intermittent intravenous administration, whereas the coumarin preparations, in spite of the risk of hæmorrhage involved, are extensively used because of low cost and ease of administration Burt et al (1949) have reported trials on a new coumarin substance, bis 3, 3' (4 oxycoumarinyl) ethyl acetate ('Tromexan'), which is said to have fewer of the disadvantages of the older dicoumarol preparations

The short period of action of heparin and the ease with which it can be neutralised by fresh blood or by protamine sulphate provide a wide margin of safety which would make it the ideal anticoagulant if a method of administration at infrequent intervals by an alternative route could be used Fullerton and Anastasopoulos (1949) have emphasised that, until effective intramuscular preparations of it are available with an action lasting many hours, heparin is unlikely to be used for more than a few days at a time, and effective treatment is usually desired for a longer period

Efforts have been made to overcome these difficulties by incorporating heparin in a medium which would delay absorption when given by intramuscular injection, and Bryson and Code (1944) used a preparation in which the heparin was incorporated with beeswax It has been suggested that the action of intravenous heparin can be prolonged by the simultaneous use of 'Caronamide' (Sirak et al 1948), but caronamide can give rise to toxic effects and therefore should not be used as a routine

G P Pitkin (unpublished work cited by Loewe et al 1942) devised a medium consisting of glucose, acetic acid and gelatin to slow the rate of absorption of water soluble drugs given intramuscularly or subcutaneously Heparin was first used in this vehicle by Loewe et al (1942), who, using the subcutaneous route, produced a satisfactory increase in the coagulation time in rabbits Loewe and Rosenblatt (1944), using 200-300 mg of heparin every 48-72 hours, obtained clotting times of 25-80 minutes in fifteen patients with thrombophlebitis They noted that after a single dose of 100 mg there was a delay of several hours before any definite increase in coagulation time, but that the increase was sustained for 2-5 days

* Formerly Research Fellow and Tutor in Therapeutics University of Sheffield

Several other papers on the clinical use of heparin in Pitkin's menstuum (heparin/Pitkin) have appeared (Loewe et al 1946, Greene and Loewe 1947, Richter et al 1947, Weiner and Lange 1947, Bancroft 1947, Loewe and Hirsch 1947) The most recent paper (Loewe and Eiber 1949) refers to its use in 20 patients with acute myocardial infarction, who were given 400 mg of heparin/Pitkin every forty eight hours On this régime coagulation times (measured by the method of Lee and White) between 25 and 30 minutes were obtained in normal reactors

We have been unable to find any report of a fatality due to heparin/Pitkin, but all who have used the menstuum have commented on the local swelling, pain, and tenderness at the injection site Apparently this has never necessitated withdrawal of therapy, and the pain has been controlled with analgesics Loewe and Hirsch (1947) and Loewe and Eiber (1949) state that careful buffering is necessary to make the gel "more physiologically acceptable" and reduce the irritation Weiner and Lange (1947) found that repeated subcutaneous injections at the same site in rats and rabbits produced hæmatomata, often so large that the animals died from acute blood loss In some instances the heparin was trapped in these hæmatomata, with the result that the coagulation time of the circulating blood did not increase These workers point out that in clinical practice the risk of serious blood loss must be very much less, since the size of any hæmatoma relative to that of the total vascular bed is much smaller in man than in rabbits

Loewe and Rosenblatt (1944) have shown that compression of the thigh proximal to the site of injection will prevent further heparin from entering the circulation, and Loewe and Eiber (1949) have not required protamine to neutralise excess of heparin in the course of a large number of injections of the menstuum

Kiesewetter and Shumacker (1948) found, however, that 16 of 28 dogs to which heparin/Pitkin was given developed serious local complications with sloughing, œdema, and inflammation Bauer et al (1950), reporting on the use of soluble intramuscular heparin, state that their experience of heparin/Pitkin was unfavourable

It seems, however, that in some workers' experience, heparin/Pitkin is a safe and adequate anticoagulant The preparation used by the American workers cited had been supplied by William R Warner & Co Inc, and has not been generally available in this country We report below our experience in 24 cases treated with heparin/Pitkin made by Boots Pure Drug Co

INVESTIGATION

The clinical material consisted of cases studied in the wards of the Royal Infirmary, Sheffield, and of Hammer-smith Hospital (Postgraduate Medical School of London) 24 patients with thrombo embolic disease (venous thrombosis 8, myocardial infarction 6, pulmonary embolism 9, and arterial embolism 1) were treated with heparin/Pitkin The object of the clinical trial was primarily to assess the efficacy of heparin/Pitkin in prolongation of the coagulation time, and no specific attempt was made to investigate the effect of anti coagulant therapy in the treatment of thrombo embolic disease The patients selected for therapy were chosen because it was felt that the administration of anti coagulant substances was unjustified in the absence of clear indications for this form of therapy

METHOD

Heparin Pitkin was prepared in 2 ml. ampoules according to the following prescription

Heparin (B.P.) 20 000 I.U. (200 mg)
Gelatin (B.P.) 360 mg
Dextrose (B.P.) 160 mg
Acetic acid (B.P.) 0.03 ml.
Water to 2 ml

the mind, and the developed mind so conditions the subsequent maintenance of the brain, that the individual has difficulty in standing up to emotional strain during adolescence and is predisposed to mental breakdown in later life under mental stress or in physical ill health. In these cases there is often a family history of mental instability suggesting the transmission of a tendency to mental disease through the structure of the brain. Kiesewetter and Shumacker (1948) found, however, that 16 of 28 dogs to which heparin/Pitkin was given developed serious local complications with sloughing, œdema, and inflammation Bauer et al. (1950), reporting on the use of soluble intramuscular heparin, state that their experience of heparin/Pitkin was unfavourable

It seems, however, that in some workers' experience, heparin/Pitkin is a safe and adequate anticoagulant The preparation used by the American workers cited had been supplied by William R. Warner & Co. Inc., and has not been generally available in this country We report below our experience in 24 cases treated with heparin/Pitkin made by Boots Pure Drug Co.

INVESTIGATION

The clinical material consisted of cases studied in the wards of the Royal Infirmary, Sheffield, and of Hammett Hospital (Postgraduate Medical School of London) 24 patients with thrombo embolic disease (venous thrombosis 8, myocardial infarction 6, pulmonary embolism 9 and arterial embolism 1) were treated with heparin/Pitkin The object of the clinical trial was primarily to assess the efficacy of heparin/Pitkin in prolongation of the coagulation time, and no specific attempt was made to investigate the effect of anti-coagulant therapy in the treatment of thrombo embolic disease The patients selected for therapy were chosen because it was felt that the administration of anti-coagulant substances was unjustified in the absence of clear indications for this form of therapy

METHOD

Heparin Pitkin was prepared in 2 ml. ampoules according to the following prescription

Heparin (B.P.) 20 000 I.U. (200 mg.)
Gelatin (B.P.) 360 mg
Dextrose (B.P.) 160 mg
Acetic acid (B.P.) 0.03 ml
Water to 2 ml

* Formerly Research Fellow and Tutor in Therapeutics University of Sheffield

At room-temperature this preparation is a solid gel. It was therefore necessary to warm it to body heat and, when it became fluid, to draw it into the syringe through a wide bore needle. 1 ml. of 2% procaine (20 mg) was then drawn into the syringe, and the mixture injected slowly into a large muscle mass, the position of choice being the anterolateral aspect of the thigh. In many cases a further 1 ml of procaine was injected down the track of the needle. Care was taken to spread subsequent injections over a wide area. Coagulation-times were estimated twice daily (9.30 A.M. and 4.30 P.M.) by Lee and White's method, which has a normal range of 2-10 minutes. The aim of treatment was to obtain average coagulation times of 20-25 minutes, a range considered to be satisfactory by Allen et al (1946). The drug was injected at noon only, or at noon and at midnight when, as became usual, twice daily injections were necessary.

After some unfavourable experience with subcutaneous injections as used by American workers, we invariably used the intramuscular route. The injection should never be given in a part of a limb which is in the least degree cedematous or in which there is evidence of poor venous circulation, because the absorption in such cases is irregular and erratic.

RESULTS

The results are tabulated in the accompanying table. It can be seen that all patients except three (cases 17, 22, and 23) showed a satisfactory response with prolongation of the coagulation time. Case 17 was completely resistant to doses of up to 1 g daily, no significant alteration in coagulation time occurring. Local reactions in this case were slight, hence there seemed no reason to doubt that the heparin was reaching the general circulation. Satisfactory prolongation of the coagulation

RESULTS OF TREATMENT WITH HEPARIN/PITKIN IN THROMBO-EMBOLIC DISEASE

Case no	Sex	Age (yr.)	Diagnosis	Duration of treatment (days)	Average dosage (mg.)	Average coagulation time (Lee and White) (min.)	Remarks
1	F	57	Myocardial infarction	25	400 on alternate days	12-16	Inadequate dosage recovery
2	M	53	Pulmonary embolism	21	See fig 1		Poor levels until dosage increased, recovery
3	F	61	Pulmonary embolism	15	200-400 12 hrly	16-24	Rather uneven levels, recovery
4	M	57	Phlebothrombosis	3	400 12 hrly	20	Very satisfactory, drug only used at end of course of intravenous heparin recovery
5	M	45	Pulmonary embolism	10	200 12 hrly	24	Satisfactory therapy, but rather painful, good levels recovery
6	F	38	Phlebothrombosis	5	200 12 hrly	20	Satisfactory coagulation times, but treatment stopped because of pain and hematoma
7	M	42	Phlebothrombosis, pulmonary embolism	4	See fig 3		Treatment stopped because of hematuria
			(Second course)	13	200-400 12 hrly	16-24	Irregular absorption and levels, continued to have pulmonary emboli died
8	M	63	Pulmonary embolism	11	See fig 2(A)		Satisfactory, little pain recovery
9	M	48	Phlebothrombosis pulmonary embolism	9	See fig 4		Irregular absorption, large local hematoma, treatment discontinued, recovery
10	F	44	Myocardial infarction	12	200 12 hrly	16-28	Satisfactory coagulation times no complication but patient died after further infarction
11	M	65	Phlebothrombosis	7	200 12 hrly	20-24	Satisfactory little discomfort, recovery
12	M	62	Myocardial infarction	13	See fig 2(b)		Fairly satisfactory very little pain or discomfort, recovery

Fig 1—Pulmonary embolism in a man aged 53 (case 2) showing inadequacy of dosage until heparin/Pitkin was given twice daily. Recovery

time was not obtained in case 22, and local pain associated with a larger dose necessitated the substitution of intravenous heparinisation. Even with 50 mg three hourly intravenously this patient showed resistance to the drug. Case 23 developed large haematomata at the sites of injection, so the treatment had to be stopped before an effective dosage had been reached. The dosage used varied from 2 ml (200 mg) twelve hourly to 4 ml (400 mg) twelve hourly. In case 1 200 mg every forty-eight hours was tried but found to be inadequate, as was 400 mg every twenty four hours. Experience with this case and with case 2 (fig 1) showed that twelve hourly injections were necessary to achieve and maintain a satisfactory coagulation time. Subsequently all cases were given 200 mg twelve hourly initially, and this dose was increased to 400 mg twelve hourly when necessary. Treatment was continued for at least 10–14 days whenever possible. In most cases fluctuations occurred

curves illustrate several points which we noted in our experience with heparin/Pitkin. Firstly, it was often necessary to use during the first few days a slightly higher dosage than might subsequently be necessary to maintain adequately prolonged coagulation times. If it became necessary subsequently to increase the daily dosage of heparin/Pitkin to attain levels previously obtainable with a lower dosage, the usual explanation was that the drug was not being adequately absorbed into the general circulation, and care was necessary to avoid its sudden release with possibly disastrous results (case 9). Secondly, a fall in the coagulation times from a previously constant level could often be remedied by the occasional isolated administration of a higher dose. Thirdly, if the patient was not intolerant of pain produced by injection of heparin/Pitkin in the first three days, it was usually possible to continue its administration for a week or more if necessary.

As the result of experience we adopted the custom of prescribing a dose of 400 mg if the coagulation time was less than 15 minutes, and 200 mg if it was 15–30 minutes, and we usually withheld the next dose if the coagulation-time was more than 30 minutes.

The time required to produce an effective coagulation time after a single injection of heparin/Pitkin was very variable but never less than six hours and in some cases it was twenty four hours, during which time a second injection had been given. In view of this delay soluble heparin in addition was given initially in cases where an immediate increase in the coagulation time was urgently required. It was found advisable, moreover, to initiate treatment with heparin/Pitkin with the smallest potentially effective dose (200 mg), since the sensitivity of each patient could not be predicted. In case 7 the coagulation time of 6 minutes was not increased after 200 mg but rose to 60 minutes after a further 400 mg twelve hours later (fig 3). Probably variations in both heparin tolerance and rate of absorption influenced these results.

Complications

In practically every case some bruising and tenderness developed at the injection site after each injection. In 6 cases this local reaction was severe enough to stop the treatment. In 1 further case (case 7, fig 3) haematuria occurred while the coagulation time was 34 minutes but

Fig 3—Phlebotrombosis and pulmonary emboli in a man aged 42 (case 7) showing initial response to treatment with heparin Pitkin which was discontinued because of haematuria. Patient eventually died after massive pulmonary embolism

Fig 2—A pulmonary embolism in a man aged 63 (case 8) treated with heparin/Pitkin for 11 days showing how a transient fall in the mean coagulation-time can be boosted by an occasional injection at a higher dosage. Recovery. B myocardial infarction in a man aged 62 (case 12) treated with heparin/Pitkin for 13 days. Recovery. C myocardial infarction in a man aged 49 (case 14) treated with heparin/Pitkin for 11 days. Death followed further infarction.

At room temperature this preparation is a solid gel. It was therefore necessary to warm it to body heat and, when it became fluid, to draw it into the syringe through a wide bore needle. 1 ml of 2% procaine (20 mg) was then drawn into the syringe, and the mixture injected slowly into a large muscle mass, the position of choice being the anterolateral aspect of the thigh. In many cases a further 1 ml of procaine was injected down the track of the needle. Care was taken to spread subsequent injections over a wide area. Coagulation-times were estimated twice daily (9.30 A.M. and 4.30 P.M.) by Lee and White's method, which has a normal range of 2-10 minutes. The aim of treatment was to obtain average coagulation times of 20-25 minutes, a range considered to be satisfactory by Allen et al (1946). The drug was injected at noon only, or at noon and at midnight when, as became usual, twice daily injections were necessary.

After some unfavourable experience with subcutaneous injections as used by American workers, we invariably used the intramuscular route. The injection should never be given in a part of a limb which is in the least degree cedematous or in which there is evidence of poor venous circulation, because the absorption in such cases is irregular and erratic.

RESULTS

The results are tabulated in the accompanying table. It can be seen that all patients except three (cases 17, 22, and 23) showed a satisfactory response with prolongation of the coagulation time. Case 17 was completely resistant to doses of up to 1 g daily, no significant alteration in coagulation time occurring. Local reactions in this case were slight, hence there seemed no reason to doubt that the heparin was reaching the general circulation. Satisfactory prolongation of the coagulation

RESULTS OF TREATMENT WITH HEPARIN/PITKIN IN THROMBO-EMBOLIC DISEASE

Case no	Sex	Age (yr.)	Diagnosis	Duration of treatment (days)	Average dosage (mg)	Average coagulation time (Lee and White) (min.)	Remarks
1	F	57	Myocardial infarction	25	400 on alternate days	12-16	Inadequate dosage recovery
2	M	53	Pulmonary embolism	21	See fig 1		Poor levels until dosage increased, recovery
3	F	61	Pulmonary embolism	15	200-400 12 hrly	16-24	Rather uneven levels, recovery
4	M	57	Phlebothrombosis	2	400 12 hrly	20	Very satisfactory, drug only used at end of course of intravenous heparin, recovery
5	M	45	Pulmonary embolism	10	200 12 hrly	24	Satisfactory therapy but rather painful, good levels, recovery
6	F	38	Phlebothrombosis	5	200 12 hrly	20	Satisfactory coagulation times, but treatment stopped because of pain and hematoma
7	M	42	Phlebothrombosis pulmonary embolism	4	See fig 3		Treatment stopped because of hematuria
			(Second course)	13	200-400 12 hrly	16-24	Irregular absorption and levels, continued to have pulmonary emboli died
8	M	63	Pulmonary embolism	11	See fig 2(A)		Satisfactory, little pain recovery
9	M	48	Phlebothrombosis pulmonary embolism	9	See fig 4		Irregular absorption, large local hematoma, treatment discontinued recovery
10	F	44	Myocardial infarction	12	200 12 hrly	16-28	Satisfactory coagulation times no complication but patient died after further infarction
11	M	65	Phlebothrombosis	7	200 12 hrly	20-24	Satisfactory, little discomfort recovery
12	M	62	Myocardial infarction	13	See fig 2(b)		Fairly satisfactory - very little pain or discomfort recovery
13	F	54	Bilateral deep femoral venous thrombosis	2	200 12 hrly	18	Spreading oedema left no suitable injection site in legs painful in shoulder muscle mass, discontinued, recovery
14	M	49	Myocardial infarction	11	See fig 2(c)		Satisfactory, but patient died after further infarction
15	M	37	Pulmonary embolism	8	200-400 12 hrly	17-22	Some local discomfort only recovery
16	M	63	Pulmonary embolism	10	200 12 hrly	16-20	Satisfactory, but some local discomfort, recovery
17	F	60	Mitral stenosis, auricular fibrillation femoral embolus	7	200-400 12 hrly	7-12	Resistant no prolongation of coagulation time died
18	F	63	Thrombophlebitis of calf	6	200 12 hrly	15-20	Fairly satisfactory, normal coagulation time only 1 min recovery
19	M	69	Myocardial infarction	8	400 24 hrly	15-24	Treatment stopped because of local pain and discoloration pyrexia
20	M	47	Myocardial infarction	5	200-400 12 hrly	16	Treatment stopped because of severe local reaction and hematoma, albuminuria pyrexia
21	M	59	Pelvic venous thrombosis	7	100-200 12 hrly	17-30	Very sensitive died after ligation of inferior vena cava
22	M	55	Pulmonary embolism	4	200-400 12 hrly	12-14	Resistant local reaction when dose was raised
23	F	48	Mitral stenosis pulmonary emboli	4	200 12 hrly	8-15	Treatment stopped because of large hematoma died in congestive heart failure
24	F	74	Pulmonary embolism	3	100-200 12 hrly	20-30	Very sensitive treatment stopped recovery

Attention is drawn to the danger of blood loss into injection sites and sudden release into the circulation of large amounts of heparin

Heparin/Pitkin is suitable for general use only if careful watch is kept for excessive local reactions and if the coagulation time is estimated every twenty four hours

In patients who have no more than mild local reactions, the menstruum is a satisfactory and convenient medium for anticoagulant therapy and has many advantages over intravenous soluble heparin and dicoumarol

Further work is necessary to modify the menstruum so as to diminish local reactions and ensure more even absorption of heparin

We wish to thank Prof E J Wayne for his help, members of the staff of Sheffield Royal Infirmary, for referring suitable cases for treatment, Dr Joyce Burke, Dr K A Spittlehouse, and Dr J P Green for their assistance Messrs Boots Pure Drug Co Ltd for supplies of heparin in Pitkin's menstruum, and Mr A. G. Barnitt for the charts

ACTIVITY OF HEPARIN IN PITKIN'S MENSTRUUM

J D MUIR

M.B Lpool, F.R.C.S.E

SENIOR SURGICAL OFFICER, ST JOHN'S HOSPITAL, CHELMSFORD

To delay the absorption of heparin, Loewe and Rosenblatt (1944) and Lange and Loewe (1946) gave it in Pitkin's menstruum by deep subcutaneous injection, and the effect of a single dose often lasted one to six days. I have been unable to confirm their findings in a small series of cases, but the preparation is useful in thrombo embolic conditions requiring an anticoagulant

Pitkin's menstruum is a mixture of gelatin, glucose, icetic acid, and water, solid at room temperature but readily melted by warming to 45–50°C. The menstruum is made up in 2 ml ampoules already incorporated with 200 mg (200,000 i.u.) of heparin. It is readily administered by warming the ampoule and drawing the contents into a warm dry syringe immediately before the injection, which is given deeply into the subcutaneous tissues

Before the preparation was used clinically its action was assessed on volunteers, heparin activity being

determined by repeated estimations of coagulation time. These were done by placing 1 ml of blood, obtained by clean venepuncture, in a test tube of 8 mm diameter and inverting it every half-minute. The coagulation time is taken when the blood clots to such an extent that on inversion it remains at the end of the tube or falls en masse, the normal is 3–10 minutes. From its withdrawal the blood must not be agitated

Fig 1—Effect of heparin 300 mg in Pitkin's menstruum on coagulation time in six healthy volunteers

PRELIMINARY INVESTIGATION

The optimal preliminary dose is usually 200–400 mg of heparin. In six volunteers 300 mg of heparin in Pitkin's menstruum was given by deep subcutaneous injection and the coagulation times were taken after nine, fifteen, and twenty one hours (fig 1). The 9 hour coagulation-time was prolonged to 15–30 minutes in five of the cases, but in the sixth the effect was much greater and lasted up to twenty one hours. Slight discomfort was felt at the site of the injection, but no untoward reactions occurred

Fig 2—Effect of protamine sulphate on activity of heparin

Since anticoagulant drugs are potentially dangerous the effectiveness of protamine sulphate as an antidote was next investigated. In two other volunteers, when a satisfactory response had been obtained, 10 ml. of 1% protamine sulphate solution was injected intravenously and the coagulation time determined five minutes later. In both cases the coagulation time fell sharply (fig 2). This effect would probably not last long enough to

-Phlebotrombosis and pulmonary emboli in a man aged 48 (9) showing sudden rise in coagulation time consequent on use of heparin from a large haematoma. Treatment discontinued very

was no local haematoma. The severe local reactions the form of large haematomata in 3 cases (cases 6, 23), and gross painful swelling of the thigh associated with pyrexia and leucocytosis in 2 cases (cases 19, 20). Case 20 developed profuse proteinuria for four hours, but there was no haematuria and no rise in the amount of haemoglobin. These systemic reactions were not due to sensitivity to heparin, since patients subsequently received intravenous soluble heparin without untoward effect. Severe local discomfort at obvious cause led to stopping of the treatment in 2 after the dosage had been raised.

al bleeding at the site of the injection, with sudden into the circulation of large amounts of heparin resultant severe blood loss into the site, developed as 6 and 9. In case 9 (fig 4) the Hb level fell from 89 to 57% and the coagulation time rose from 34 to 174 minutes after the haematoma had formed. The next dose of heparin was omitted, and the coagulation time fell to 22 minutes. The final dose of heparin/Pitkin should probably have been omitted, as the coagulation time rose from 22 to 145 minutes on the fall of the Hb level 5 ml of 1% protamine was given intravenously, and the coagulation time fell to 10 minutes. In case 7 (fig 3), although there was no haematoma, the injections were given in a small area, and so a large quantity of heparin may have been released suddenly into the circulation.

From these 7 cases in which local or systemic reactions or haematuria led to immediate stopping of the treatment, it was discontinued in another patient (case 14), who was very sensitive to small doses and in whom it was felt that more reliable control would be obtained with intravenous heparin. In most, but not all, the remaining cases local transient discomfort was sufficient to excite comment from the patient but not sufficient to stop treatment.

The incidence and severity of local reactions were in line with those described by workers in the United States, using heparin/Pitkin manufactured by William R. Rorer and Co. Inc., and apparently identical with that used by Boots Pure Drug Co. and used by us. In 12 cases 6 patients died: 2 from repeated pulmonary emboli (cases 7 and 22), 2 from myocardial infarction (cases 6 and 14), and 2 from congestive heart failure (cases 17 and 23). With the above mentioned exceptions there were no other untoward events, and no deaths occurred as a result of heparin/Pitkin treatment. In

those who died as the result of further thrombo embolic phenomena the coagulation times were adequately prolonged, and no ante mortem mural thrombi were found in the hearts of the 2 patients who had fatal myocardial infarction.

CONCLUSIONS

Intramuscular heparin/Pitkin 200-400 mg twelve hourly causes satisfactory lengthening of the coagulation time and is a simple and relatively safe anticoagulant, obviating the need for continuous or discontinuous intravenous administration of soluble heparin. There is a latent period of at least six hours before heparin/Pitkin takes effect, and, if immediate prolongation of the coagulation time is required, intravenous heparin must be given initially in addition. The coagulation time fluctuates considerably from day to day in the same patient, and there is a great individual variation in the degree of tolerance to this, as to other forms of heparin. The rate of absorption is irregular, and the dosage required cannot be accurately predicted beforehand. Heparin/Pitkin should not, therefore, be used unless there are adequate facilities for estimating the coagulation time, and it is unsuitable for domiciliary use except in very exceptional circumstances.

The severity of the local reactions and the tendency to extensive bleeding into the injection site are serious disadvantages. Although heparin/Pitkin is undoubtedly effective and a promising anticoagulant, it is doubtful whether its general use is practicable until the menstruum has been suitably modified, especially as regards the production of a preparation with an optimal pH, and further work to this end is necessary. In the meantime cases may be treated cautiously with an initial minimal effective dose (200 mg twelve hourly), therapy being discontinued at once in the event of more than slight local swelling, a haematoma, or a fall in the Hb level. Fresh blood for transfusion and protamine sulphate should be available. Coagulation times should be estimated at least once every forty eight hours. It must be remembered that, since heparin in this form can be rapidly neutralised by protamine and/or blood transfusion, the risk is minimal, provided that careful watch is kept on the injection sites.

The effective dose of heparin/Pitkin (200-400 mg twelve hourly) is in excess of that used by Loewe and Eiber (1949), who found 400 mg every forty eight hours to be adequate and produced consistent and predictable response from a given dose and procured satisfactory coagulation times 1 or 2 hours after a single injection.

SUMMARY

24 patients with thrombo embolic disease were treated with heparin dissolved in Pitkin's menstruum to retard absorption.

Satisfactory lengthening of the coagulation time was obtained in all except 3 cases.

Wide variations in coagulation times occurred from patient to patient, and in the same patient from day to day after a standard dose. This was attributed to differences in rate of absorption, and to individual variations in sensitivity to heparin.

The minimal effective dose was 200 mg twelve hourly, and the average was 200 mg alternating with 400 mg twelve hourly (600 mg a day).

A latent period of at least 6-48 hours occurred before adequate clotting times were obtained.

Intravenous soluble heparin was required in addition when an immediate anticoagulant effect was required.

Most patients developed some pain at the injection sites, and in 6 cases these local reactions were severe consisting of large haematomata in 3 patients and inflammatory reactions in 3.

Attention is drawn to the danger of blood loss into injection sites and sudden release into the circulation of large amounts of heparin

Heparin/Pitkin is suitable for general use only if careful watch is kept for excessive local reactions and if the coagulation time is estimated every twenty four hours

In patients who have no more than mild local reactions, the menstruum is a satisfactory and convenient medium for anticoagulant therapy and has many advantages over intravenous soluble heparin and dicoumarol

Further work is necessary to modify the menstruum so as to diminish local reactions and ensure more even absorption of heparin

We wish to thank Prof E J Wayne for his help, members of the staff of Sheffield Royal Infirmary for referring suitable cases for treatment, Dr Joyce Burke, Dr K. A. Spittlehouse, and Dr J P Green for their assistance Messrs Boots Pure Drug Co Ltd. for supplies of heparin in Pitkin's menstruum and Mr A. G. Barnitt for the charts

ACTIVITY OF HEPARIN IN PITKIN'S MENSTRUUM

J D MUIR

MB Lpool, FRCS(E)

SENIOR SURGICAL OFFICER ST JOHN'S HOSPITAL, CHELMSFORD

To delay the absorption of heparin, Loewe and Rosenblatt (1944) and Lange and Loewe (1946) gave it in Pitkin's menstruum by deep subcutaneous injection, and the effect of a single dose often lasted one to six days. I have been unable to confirm their findings in a small series of cases, but the preparation is useful in thrombo embolic conditions requiring an anticoagulant

Pitkin's menstruum is a mixture of gelatin, glucose, acetic acid, and water, solid at room temperature but readily melted by warming to 45–50°C. The menstruum is made up in 2 ml ampoules already incorporated with 200 mg (200 000 I.U.) of heparin. It is readily administered by warming the ampoule and drawing the contents into a warm dry syringe immediately before the injection, which is given deeply into the subcutaneous tissues

Before the preparation was used clinically its action was assessed on volunteers, heparin activity being

determined by repeated estimations of coagulation time. These were done by placing 1 ml. of blood, obtained by clean venepuncture, in a test-tube of 8 mm diameter and inverting it every half-minute. The coagulation time is taken when the blood clots to such an extent that on inversion it remains at the end of the tube or falls en masse, the normal is 3–10 minutes. From its withdrawal the blood must not be agitated

Fig 1—Effect of heparin 300 mg in Pitkin's menstruum on coagulation time in six healthy volunteers

PRELIMINARY INVESTIGATION

The optimal preliminary dose is usually 200–400 mg of heparin. In six volunteers 300 mg of heparin in Pitkin's menstruum was given by deep subcutaneous injection and the coagulation times were taken after nine, fifteen, and twenty one hours (fig 1). The 9 hour coagulation time was prolonged to 15–30 minutes in five of the cases, but in the sixth the effect was much greater and lasted up to twenty-one hours. Slight discomfort was felt at the site of the injection, but no untoward reactions occurred

Fig 2—Effect of protamine sulphate on activity of heparin.

Since anticoagulant drugs are potentially dangerous the effectiveness of protamine sulphate as an antidote was next investigated. In two other volunteers, when a satisfactory response had been obtained, 10 ml. of 1% protamine sulphate solution was injected intravenously and the coagulation time determined five minutes later. In both cases the coagulation time fell sharply (fig 2). This effect would probably not last long enough to

counteract the heparin released from the subcutaneous deposit some hours later, but it was reassuring to know that a rising coagulation time could easily be controlled. The value of protamine in this respect is in striking contrast to the unreliability of the antidotes used against the dicoumarol type of drugs. Other methods of controlling a rising coagulation time—e.g., by applying a light tourniquet proximal to the injection, and by applying ice bags to resolidify the deposit of heparin—were not investigated.

CLINICAL APPLICATION

When an anticoagulant is required the need is urgent and a rapid effect is best obtained by injecting 8000–10,000 I.U. of aqueous heparin intravenously, and 100–400 mg. of heparin/Pitkin subcutaneously. A further dose of aqueous heparin may be required after three hours if a low coagulation time reveals that absorption of heparin from the Pitkin's menstruum has not yet become effective. At the end of twelve hours the patient's response to heparin can be accurately assessed. In a few cases heparin/Pitkin was given as the sole anticoagulant, its effect being controlled by determining the coagulation time every six hours for the first twenty-four hours (see table).

All the cases were given an initial dose of 400 mg. of heparin/Pitkin, and at the end of twelve hours a decision was made on further dosage. As a working rule, after twelve hours the initial dose was repeated if the coagulation time was less than double, and half this dose was given if it was between two and three times the initial coagulation time. After twenty-four hours the dosage was reviewed again in the same way.

As will be seen from the table, a single dose of heparin/Pitkin did not produce a satisfactory response for longer than twenty-four hours. At the end of this time the dosage could be satisfactorily judged, so coagulation times were determined at twelve or twenty-four hours according to the estimated frequency of dosage.

Treatment was continued for five to ten days, and one of the patients needed any change in dosage after the first day.

DISCUSSION

In many quarters dicoumarol and allied drugs are falling into disfavour because of the difficulties encountered in estimating dosage in relation to the prothrombin level. The frequent intravenous injection of heparin is the safest and most popular anticoagulant method, but unless the injections are given three hourly the coagulation time cannot be kept at a suitably raised level. Nevertheless, from the point of view of simplicity, there is a place in clinical practice for a long-acting anticoagulant with a wide margin of safety and easy to control. Heparin/Pitkin seems to be a step towards this ideal anticoagulant, although it is disappointing that the earlier reports on its activity have not been sustained. However, further experience in making up the preparation may lead to improvement in this respect.

SUMMARY

By administering heparin in Pitkin's menstruum (an aqueous solution of gelatin, glucose, and acetic acid) the effect of a single deep subcutaneous injection can be made to last 12–24 hours. The release and effect of heparin can be controlled if necessary with intravenous protamine sulphate.

A satisfactory clinical response has been obtained in untalented cases.

I wish to thank Dr J. P. Whitehead for his help with the laboratory investigations and Messrs Boots Pure Drug Co. for supplying the heparin in Pitkin's menstruum ('Heparin retard').

TREATMENT OF DEAFNESS AND RECURRENT OTITIS MEDIA WITH X RAYS

H. S. KANDER

CONSULTANT
RADIO-THERAPIST

It has long been recognised that lymphoid tissue in the nasopharynx, particularly round the orifice of the eustachian tubes and in Rosenmueller's fossa interferes with the ventilation of the middle ear and often impairs hearing. Hence the satisfactory results obtained by surgical removal of adenoids in many children with defective hearing. In a substantial proportion of cases, however, the deafness persists or recurs, or acute otitis media—catarrhal or suppurative—returns repeatedly, in spite of thorough curettage of the adenoid tissue. Such failures are due not only to the notorious tendency of adenoid tissue to reform, but also to the fact that it is often inaccessible in the place where its removal is most necessary—namely, at the orifice and in the lumen of the tube itself.

Fortunately lymphoid tissue is radiosensitive, and attempts have therefore been made to reduce excessive lymphoid tissue in the nasopharynx by irradiation.

Crowe and his co-workers (1933, 1939, 1941) introduced radium or radon applicators through the nose and placed them against the orifice of the eustachian tubes. The 'Monel' metal applicators containing 50 mg. of radium are inserted for twelve minutes every two weeks for three or more treatments. Fowler (1946), who also uses this treatment for otitic baro-trauma, employs a similar applicator with a platinum wall, which has to be left in position for about forty minutes.

Desjardins (1931, 1932) reviewing the literature concluded that X rays influence tinnitus and improve hearing in some cases. O'Brien (1937) treated 140 patients between 1929 and 1935 and found that 73 had improved hearing, 65 were unchanged, and 2 were worse. Rentschler and Settle (1944) describe the technique they employed in 19 patients who had deafness and middle ear disease, using a total of 800 r. 15 of their patients were improved and 8 had their hearing restored to normal. Hawley (1944) reports 18 cases with impaired hearing, of which 17 showed improvement audiometrically. Young and Woutat (1948) review the literature and give their experience with deep X ray therapy in 116 cases. They consider it the treatment of choice for chronic middle ear infection with lymphoid infiltration of the eustachian tubes, and in cases of deafness associated with excessive lymphoid tissue, and recurrent otitis media. They observed no damage to surrounding structures.

In the United States irradiation by radium or radon applicators is now widely practised and has become standardised. In this country this method is now being tried. When we considered irradiation treatment nearly three years ago radium applicators were not available to us, and we therefore started the less popular method of treatment by deep X rays. Impressed by the good results in our early cases we pursued this method. It seemed to us that the repeated insertion of applicators into the nose must be an unpleasant procedure, and in children it often requires general anaesthesia. We did not think this justifiable if the same results could be obtained by an easier method.

In our experience it has not been difficult to treat even nervous children by X rays. Apart from 2 cases which developed mild parotitis lasting a few days, our patients have had no side effects. (It should be noted, however, that the dose given may cause temporary depilation over the temples, unless the hairy part of the scalp is screened with lead rubber.) No skin erythema has been seen, and no complaints of dryness of the throat have been made. One child treated for recurrent otitis media and deafness had an acute attack of otitis media

three weeks after treatment, but we have no evidence that the irradiation was a contributing factor

Fowler (1947), one of the advocates of the radium method, admits that comparable results can be obtained by deep X-ray therapy. His objections to it are the possibility of flare ups of otitis media, occasional parotitis, and the need for cumbersome and expensive equipment and the services of a radiotherapist. In view of the availability of deep X-ray equipment in most large hospitals the last argument is scarcely valid. In any case we feel that the supervision of a radiotherapist is essential in any form of radiotherapy. Fowler also states that where lymphoid tissue grows excessively, and radiotherapy by radium or radon to the mouth of the tube is unsuccessful, deep X-ray therapy may be required to shrink it.

Dickson and McGibbon (1949) writing on the treatment of otitic barotrauma, strongly prefer deep X-rays to radium, which they regard as dangerous in the dosage which would be needed for irradiation of the entire eustachian tube.

SELECTION OF CASES

The correct selection of cases for radiotherapy is of great importance. On routine examination of a large number of children Crowe found that the first indication of hearing loss due to excessive lymphoid tissue is impairment of hearing of very high tones, well above the speech range and in the neighbourhood of 16,000 d.v.s. (double vibrations per sec). This hearing loss may be caused by lesions other than tubal occlusion but he advises treatment prophylactically if the nasopharynx is not completely normal. The best results from radiotherapy were obtained, however, in cases in which

TABLE I—DEAFNESS RESULTS OF TREATMENT

	Total	Improvement		No change	% improved
Clinical and symptomatic	31	28 (90.3%)		3 (9.7%)	90.3
Audiometric	27	Marked 10 (37%)	Slight 11 (40.7%)	6 (22.3%)	77.7

hearing was impaired for all tones in children who had difficulty in understanding the spoken voice.

It is clear that early treatment is imperative if permanent changes—e.g. adhesions in the middle ear and marked retraction of the tympanic membranes—are to be prevented. Once these changes have occurred the process is irreversible and may even progress. It is therefore of utmost importance that a suspicion of deafness by parents or teachers should be taken seriously. All these cases should be investigated thoroughly and referred to an otologist, who should look for aural, nasopharyngeal, or nasal abnormality. Hearing tests with the audiometer and spoken voice may have to be made repeatedly before any objective evidence of deafness can be obtained. In many cases removal of tonsils and adenoids will have to be the first therapeutic measure but often these have already been removed. When after careful operative removal marked lymphoid enlargement is present, especially on the posterior pharyngeal wall and in the nasopharynx, and in patients who give a history of frequent colds, earache, or recurrent otitis media, hearing should be assessed carefully. Occasionally one sees cases in which a large pad of adenoids has recurred. This should be removed surgically, because great shrinkage may not take place with the dosage of X-rays used.

To avoid disappointments the selection of cases for radiotherapy should be narrowed down to those fulfilling certain criteria. Our two main groups were children suffering from deafness and those suffering from recurrent

attacks of otitis media. All these children treated by deep X-rays had had their tonsils and adenoids removed—almost all of them long before they were referred to us for deafness, &c. Excessive lymphoid tissue was present either in the postnasal space or around the openings of the eustachian tubes. In some children we were unable to see the postnasal space by mirror examination, and in those the lymphatic nodules on the posterior pharyngeal wall were conspicuous, or there was enlargement of the lateral pharyngeal bands, two red bands of lymphoid tissue just behind the posterior tonsillar pillars. The tympanic membranes were usually retracted or had lost some of their lustre, both in our deafness cases and in those suffering from attacks of acute otitis media with or without discharge.

TABLE II—RECURRENT AND CHRONIC OTITIS MEDIA RESULTS OF TREATMENT

Total no	Improved	No change
21	16 (76.2%)	5 (23.8%)

One patient had an anterior perforation of the tympanic membrane with a chronic discharge. In all but 3 of our cases audiograms were taken before and after treatment, and, though we did not find a drop at the 16,000 d.v.s. level, which Crowe considered of such significance, some hearing loss could be demonstrated audiometrically in all our deafness cases. In some this loss was only slight and in the neighbourhood of 15–20 decibels but treatment was nevertheless given when the other criteria were present as well.

Though we regarded the audiometric testing as a valuable scientific means of assessing hearing loss, we fully recognise that it is only partially reliable. Tests often take a considerable time, and fatigue and the temperament of the child may influence the result and value of the test. Therefore information from the parents about their child's hearing is of great importance.

TECHNIQUE

We used a deep X-ray therapy plant calibrated at 200 kV, 10 mA, Thoraeus filter, 50 f.s.d., half-value layer corresponding to 2 mm Cu. The applicators were usually 8 × 6 cm or 6 × 4 cm using two lateral fields to both sides of the face. The centring point in the first few cases was found by taking X-ray films of the skull with a eustachian catheter in position. The point on the skin is on an average 2 cm in front of the external auditory meatus. The hairy part of the scalp was protected by lead rubber of approximately triangular shape with the apex of the triangle pointing downwards.

TABLE III—FREQUENT COLDS AND NASAL OBSTRUCTION BY LYMPHOID TISSUE RESULTS OF TREATMENT

Total no	Marked improvement	Slight improvement	No change
8	7	2	0

The treatment was given on five successive days and the dose aimed at the eustachian tubes and nasopharynx was 200 r from both fields in each exposure the total dose given being 1000 r. On one occasion where the child had on commencement of the treatment, an acute otitis media, two weekly exposures were given for three weeks with the same total dosage and with a very satisfactory result. This made us think that in some cases a prolonged fractional treatment may have advantages especially in cases in an acute stage.

The patient lies supine with the head turned to one side with the central beam at right-angles to the plane

counteract the heparin released from the subcutaneous deposit some hours later, but it was reassuring to know that a rising coagulation time could easily be controlled. The value of protamine in this respect is in striking contrast to the unreliability of the antidotes used against the dicoumarol type of drugs. Other methods of controlling a rising coagulation time—e.g. by applying a light tourniquet proximal to the injection and by applying ne-bags to resolidify the deposit of heparin—were not investigated.

CLINICAL APPLICATION

When an anticoagulant is required the need is urgent and a rapid effect is best obtained by injecting 8000–10,000 I.U. of aqueous heparin intravenously, and 300–400 mg. of heparin Pitkin subcutaneously. A further dose of aqueous heparin may be required after three hours if a low coagulation time reveals that absorption of heparin from the Pitkin's menstruum has not yet become effective. At the end of twelve hours the patient's response to heparin can be accurately assessed. In a few cases heparin Pitkin was given as the sole anticoagulant, its effect being controlled by determining the coagulation-time every six hours for the first twenty-four hours (see table).

All the cases were given an initial dose of 400 mg. of heparin/Pitkin, and at the end of twelve hours a decision was made on further dosage. As a working rule after twelve hours the initial dose was repeated if the coagulation-time was less than double, and half this dose was given if it was between two and three times the initial coagulation-time. After twenty-four hours the dosage was reviewed again in the same way.

As will be seen from the table, a single dose of heparin/Pitkin did not produce a satisfactory response for longer than twenty-four hours. At the end of this time the dosage could be satisfactorily judged so coagulation-times were determined at twelve or twenty-four hours according to the estimated frequency of dosage.

Treatment was continued for five to ten days, and none of the patients needed any change in dosage after the first day.

DISCUSSION

In many quarters dicoumarol and allied drugs are falling into disfavour because of the difficulties encountered in estimating dosage in relation to the prothrombin level. The frequent intravenous injection of heparin is the safest and most popular anticoagulant method, but unless the injections are given three hourly the coagulation-time cannot be kept at a suitably used level. Nevertheless, from the point of view of simplicity, there is a place in clinical practice for a long-acting anticoagulant with a wide margin of safety and easy to control. Heparin/Pitkin seems to be a step towards this ideal anticoagulant, although it is disappointing that the earlier reports on its activity have not been sustained. However, further experience in making up the preparation may lead to improvement in this respect.

SUMMARY

By administering heparin in Pitkin's menstruum (an aqueous solution of gelatin, glucose, and acetic acid) the effect of a single deep subcutaneous injection can be made to last 12–24 hours. The release and effect of heparin can be controlled if necessary with intravenous protamine sulphate.

A satisfactory clinical response has been obtained in suitable cases.

I wish to thank Dr J. P. Whitehead for his help with the laboratory investigations and Messrs Boots Pure Drug Co. for supplying the heparin in Pitkin's menstruum (Heparin Retard).

RADIOTHERAPIST

It has long been recognised that lymphoid tissue in the nasopharynx, particularly round the orifice of the eustachian tubes and in Rosenmueller's fossa interferes with the ventilation of the middle ear and often impairs hearing. Hence the satisfactory results obtained by surgical removal of adenoids in many children with defective hearing. In a substantial proportion of cases, however, the deafness persists or recurs, or acute otitis media—catarrhal or suppurative—returns repeatedly, in spite of thorough curettage of the adenoid tissue. Such failures are due not only to the notorious tendency of adenoid tissue to reform, but also to the fact that it is often inaccessible in the place where its removal is most necessary—namely, at the orifice and in the lumen of the tube itself.

Fortunately lymphoid tissue is radiosensitive, and attempts have therefore been made to reduce excessive lymphoid tissue in the nasopharynx by irradiation.

Crowe and his co-workers (1938, 1939, 1941) introduced radium or radon applicators through the nose and placed them against the orifice of the eustachian tubes. The Monel metal applicators containing 50 mg. of radium are inserted for twelve minutes every two weeks for three or more treatments. Fowler (1946), who also uses this treatment for otitic barotrauma, employs a similar applicator with a platinum wall, which has to be left in position for about forty minutes.

Dequardus (1931, 1932) reviewing the literature concluded that X rays influence tinnitus and improve hearing in some cases. O'Brien (1937) treated 140 patients between 1929 and 1935 and found that 73 had improved hearing, 65 were unchanged and 2 were worse. Rentschler and Settle (1944) describe the technique they employed in 19 patients who had deafness and middle-ear disease, using a total of 800 r. 15 of their patients were improved and 8 had their hearing restored to normal. Hawley (1944) reports 15 cases with impaired hearing, of which 17 showed improvement audiometrically. Young and Woutat (1948) review the literature and give their experience with deep X ray therapy in 116 cases. They consider it the treatment of choice for chronic middle ear infection with lymphoid infiltration of the eustachian tubes, and in cases of deafness associated with excessive lymphoid tissue, and recurrent otitis media. They observed no damage to surrounding structures.

In the United States irradiation by radium or radon applicators is now widely practised and has become standardised. In this country this method is now being tried. When we considered irradiation treatment nearly three years ago radium applicators were not available to us, and we therefore started the less popular method of treatment by deep X rays. Impressed by the good results in our early cases we pursued this method. It seemed to us that the repeated insertion of applicators into the nose must be an unpleasant procedure, and in children it often requires general anaesthesia. We did not think this justifiable if the same results could be obtained by an easier method.

In our experience it has not been difficult to treat even nervous children by X rays. Apart from 2 cases which developed mild proctitis lasting a few days, our patients have had no side effects. (It should be noted, however, that the dose given may cause temporary depilation over the temples, unless the hairy part of the scalp is screened with lead rubber.) No skin erythema has been seen, and no complaints of dryness of the throat have been made. One child treated for recurrent otitis media and deafness had an acute attack of otitis media

three weeks after treatment, but we have no evidence that the irradiation was a contributing factor

Fowler (1947), one of the advocates of the radium method, admits that comparable results can be obtained by deep X ray therapy. His objections to it are the possibility of flare ups of otitis media occasional parotitis, and the need for cumbersome and expensive equipment and the services of a radiotherapist. In view of the availability of deep X-ray equipment in most large hospitals the last argument is scarcely valid. In any case we feel that the supervision of a radiotherapist is essential in any form of radiotherapy. Fowler also states that where lymphoid tissue grows excessively, and radiotherapy by radium or radon to the mouth of the tube is unsuccessful, deep X ray therapy may be required to shrink it.

Dickson and McGibbon (1949) writing on the treatment of otitic barotrauma, strongly prefer deep X rays to radium, which they regard as dangerous in the dosage which would be needed for irradiation of the entire eustachian tube.

SELECTION OF CASES

The correct selection of cases for radiotherapy is of great importance. On routine examination of a large number of children Crowe found that the first indication of hearing loss due to excessive lymphoid tissue is impairment of hearing of very high tones, well above the speech range and in the neighbourhood of 16,000 d.v.s (double vibrations per sec). This hearing loss may be caused by lesions other than tubal occlusion, but he advises treatment prophylactically if the nasopharynx is not completely normal. The best results from radiotherapy were obtained, however, in cases in which

TABLE I—DEAFNESS RESULTS OF TREATMENT

	Total	Improvement	No change	% improved

hearing was impaired for all tones in children who had difficulty in understanding the spoken voice.

It is clear that early treatment is imperative if permanent changes—e.g. adhesions in the middle ear and marked retraction of the tympanic membranes—are to be prevented. Once these changes have occurred the process is irreversible and may even progress. It is therefore of utmost importance that a suspicion of deafness by parents or teachers should be taken seriously. All these cases should be investigated thoroughly and referred to an otologist, who should look for aural, nasopharyngeal or nasal abnormality. Hearing tests with the audiometer and spoken voice may have to be made repeatedly before any objective evidence of deafness can be obtained. In many cases removal of tonsils and adenoids will have to be the first therapeutic measure but often these have already been removed. When, after careful operative removal marked lymphoid enlargement is present, especially on the posterior pharyngeal wall and in the nasopharynx, and in patients who give a history of frequent colds, earache, or recurrent otitis media, hearing should be assessed carefully. Occasionally one sees cases in which a large pad of adenoids has recurred. This should be removed surgically, because great shrinkage may not take place with the dosage of X rays used.

To avoid disappointments the selection of cases for radiotherapy should be narrowed down to those fulfilling certain criteria. Our two main groups were children suffering from deafness and those suffering from recurrent

attacks of otitis media. All these children treated by deep X rays had had their tonsils and adenoids removed—almost all of them long before they were referred to us for deafness, &c. Excessive lymphoid tissue was present either in the postnasal space or around the openings of the eustachian tubes. In some children we were unable to see the postnasal space by mirror examination, and in those the lymphatic nodules on the posterior pharyngeal wall were conspicuous, or there was enlargement of the lateral pharyngeal bands, two red bands of lymphoid tissue just behind the posterior tonsillar pillars. The tympanic membranes were usually retracted or had lost some of their lustre, both in our deafness cases and in those suffering from attacks of acute otitis media with or without discharge.

TABLE II—RECURRENT AND CHRONIC OTITIS MEDIA RESULTS OF TREATMENT

Total no	Improved	No change
21	16 (76.2%)	5 (23.8%)

One patient had an anterior perforation of the tympanic membrane with a chronic discharge. In all but 3 of our cases audiograms were taken before and after treatment, and, though we did not find a drop at the 16,000 d.v.s level, which Crowe considered of such significance, some hearing loss could be demonstrated audiometrically in all our deafness cases. In some this loss was only slight and in the neighbourhood of 15–20 decibels but treatment was nevertheless given when the other criteria were present as well.

Though we regarded the audiometric testing as a valuable scientific means of assessing hearing loss, we fully recognise that it is only partially reliable. Tests often take a considerable time, and fatigue and the temperament of the child may influence the result and value of the test. Therefore information from the parents about their child's hearing is of great importance.

TECHNIQUE

We used a deep X ray therapy plant calibrated at 200 kV, 10 mA, Thoraeus filter, 50 f.s.d., half-value layer corresponding to 2 mm Cu. The applicators were usually 8 × 6 cm or 6 × 4 cm using two lateral fields to both sides of the face. The centring point in the first few cases was found by taking X ray films of the skull with a eustachian catheter in position. The point on the skin is on an average 2 cm in front of the external auditory meatus. The hairy part of the scalp was protected by lead rubber of approximately triangular shape with the apex of the triangle pointing downwards.

TABLE III—FREQUENT COLDS AND NASAL OBSTRUCTION BY LYMPHOID TISSUE RESULTS OF TREATMENT

Total no	Marked improvement	Slight improvement	No change
8	6	2	0

The treatment was given on five successive days and the dose aimed at the eustachian tubes and nasopharynx was 200 r from both fields in each exposure the total dose given being 1000 r. On one occasion where the child had on commencement of the treatment, an acute otitis media two weekly exposures were given for three weeks with the same total dosage and with a very satisfactory result. This made us think that in some cases a prolonged fractional treatment may have advantages especially in cases in an acute stage.

The patient lies supine with the head turned to one side with the central beam at right angles to the plane

of the area to be treated. An experienced radiographer will have no difficulty in handling a child.

RESULTS

The total number of cases treated by deep X rays was 41 in a period of twenty seven months. Cases which were followed up for less than five months are not included in this series. The average follow up period was thutteen months. There were 22 male and 19 females. 39 were children from the age of four to thirteen years and the 2 other patients were seventeen and twenty six.

To assess the response we divided our cases into three groups:

1. Patients who had hearing loss (deafness).
2. Patients with recurrent otitis media with or without suppuration. (This group also included a patient with chronic suppurative otitis media with an anterior perforation due to eustachian infection.)
3. Children with frequent colds and nasal obstruction.

Several of the cases belonged to more than one group—e.g., a patient may have recurrent attacks of otitis media with loss of hearing.

Deafness

The response to treatment is assessed (1) symptomatically and clinically, and (2) audiometrically. "Symptomatic and clinical improvement" is judged by the impression of parents or teachers, improvement in school work, and our own observation. The impairment of hearing as shown by audiometer was divided into three degrees:

1. Marked: more than 20 decibels.
2. Slight: under 20 decibels.
3. No change or worse.

To assess the audiometric improvement we took the readings of a corresponding frequency at the point of the greatest loss. The results are shown in table I.

In 3 cases audiograms were not taken and in 1 case they were unreliable because the child was too vague. Of these 4, 3 showed considerable symptomatic and clinical improvement.

Fig 1 (case 1)—Audiogram on Sept. 15, 1948

Fig 2 (case 1)—Audiogram on March 30, 1949

Fig 3 (case 2)—Audiogram on Sept. 29, 1948

Fig 4 (case 2)—Audiogram on June 9, 1949

Some of the patients had only slight hearing loss audiometrically and their hearing became normal after treatment. But as the improvement was less than 20 decibels these cases are classified as showing slight improvement.

The following are reports of two cases.

Case 1—Girl aged 10. Had tonsils and adenoids removed when 4 years old. Seen first in June, 1948, because parents noticed deafness. On examination a fairly large tonsillar remnant was present on the right, and slight recurrence of adenoids could be seen. Nasal mucosa congested. Both tympanic membranes pink. Audiogram taken on Sept. 15, showed hearing loss in both ears (fig. 1). Radiography of sinuses clear. Deep X-ray therapy in October. Audiogram in November showed 10–20 decibels loss in both ears, and in March 1949 the hearing loss was less than 10 decibels (fig. 2). Hearing is now normal.

Case 2—Girl aged 6. Had tonsils and adenoids removed in 1947. Seen again in September, 1948, because of recurrent attacks of earache and otorrhœa, usually from the right ear, but also from the left. Last attack of acute otitis media in July, 1948. On examination some lymphoid follicles were present on the posterior pharyngeal wall. The right tympanic membrane was retracted and scarred, the left slightly retracted. The Rinne test was negative in both ears. Whispered voice heard from about 2 ft in both ears. An audiogram taken on Sept. 20 showed marked hearing loss in the right ear, in the left ear hearing was moderately reduced (fig. 3). X-ray therapy was started immediately. An audiogram taken on Jan. 23, 1949, showed only 10 decibels loss in both ears. On June 9, 1949, her audiogram was normal (fig. 4). Whispered voice could be heard from 12 ft without difficulty. Rinne was positive. The tympanic membranes were still retracted but there had been no earache or otorrhœa since treatment. Improvement has since been maintained.

Recurrent and Chronic Otitis Media

This group (table II) includes 1 case of chronic suppurative otitis media with an anterior perforation which dried up completely after treatment.

Case 3—Boy aged 9. Had tonsils and adenoids removed at the age of 5 in 1945. Five months later had right acute mastoiditis and operation. Intermittent earache in 1947 and cavity had to be reopened. In March, 1948, he again

had acute otitis media, with pus in scar. Paracentesis and reopening, followed by left acute otitis media. Radiography of sinuses clear. Further attack of right acute otitis media in May with swelling of scar. Deep X ray therapy in June, 1948. When seen in April, 1949, he had had no further earache or discharge. The right tympanic membrane was pale and shiny but slightly retracted. Considerable general improvement.

Colds and Nasal Obstruction

In this group (table III) 2 cases had vasomotor rhinitis and showed only slight improvement. The 6 others were treated primarily for deafness or recurrent otitis media, but had colds or nasal obstruction in addition. No conclusions as to the value of the treatment can be drawn, and we doubt whether X ray therapy is indicated unless the case belongs to one of the other two groups as well.

Most workers report almost complete shrinkage of the lymphoid tissue in the nasopharynx and round the eustachian orifices after irradiation. Some of our cases have not shown this diminution, yet their results were satisfactory. In these cases the improvement may have been due to shrinkage of lymphoid tissue inside the eustachian tube, which cannot be detected by clinical examination.

SUMMARY AND CONCLUSION

Over a period of two years, 41 cases with hypertrophy of lymphoid tissue in the nasopharynx have had deep X ray therapy.

The results were encouraging. Final conclusions cannot yet be drawn, but we are convinced that deep X ray therapy has a definite place in the treatment of selected cases of deafness and recurrent otitis media.

We wish to thank Miss M. Adamson, our hospital audiometrist, for the patience shown in testing the patients.

DEHYDRATION TREATMENT OF RHEUMATIC FEVER

W. S. C. COPEMAN

O.B.E., M.A., M.D. Camb., F.R.C.P.

PHYSICIAN TO RHEUMATISM DEPARTMENT, WEST LONDON HOSPITAL

L. G. C. E. PUGH

M.A., B.M.O. (Ed.)

MEDICAL REGISTRAR, POSTGRADUATE MEDICAL SCHOOL OF LONDON

THE mode of action of salicylates has been investigated by Reid et al. (1950), who suggest that the reduction of fever and tachycardia, together with the relief of pain and swelling in the affected joints during the first five days' therapy, can be attributed to a reduction in the water content of the body cells (dehydration). If similar clinical results were obtainable as the result of cellular dehydration brought about by another method, the basis of this hypothesis would be strengthened.

We treated 7 cases of rheumatic fever by reducing the total water content of the body and following this with a rapid intravenous injection of hypertonic saline solution to displace water from the intracellular to the extracellular fluid compartment of the body. We reported our results (1946) but did not at that time describe them in full.

The effect of this treatment on the patients was clinically comparable with that described by Reid et al.

in their cases treated with large doses of salicylates, and the side effects in our series were also strikingly similar to those which they report.

METHOD

The 7 patients treated were young soldiers serving with the B.L.A. All food and water were withheld from these patients for thirty-six hours. Six doses of sodium sulphate $\frac{1}{2}$ oz. were administered during this period. The resultant reduction in body water, estimated by loss of body-weight, amounted to 2 or 3 litres. At the end of this period 50 ml. of a 30% solution of sodium chloride (15 g.) was injected intravenously in about 30 sec. The shift of water from the cells thus produced was calculated to be about 1 litre (Gamble 1942). A cup of tea was allowed during the next four hours to mitigate thirst. The doses of sodium sulphate were continued two hourly for a further twelve hours. Twenty-four hours after the injection of sodium chloride, restriction of fluid and food was relaxed.

RESULTS

No clinical effects other than thirst and diarrhoea were observed during the preliminary period of dehydration. Within twenty-four hours after the injection of sodium chloride there was relief of pain on movement, reduction of tenderness and swelling of the affected joints, and a fall of temperature and pulse rate. Side effects, such as hyperpnoea, nausea, vomiting, and tingling of the extremities, developed in four cases, and drowsiness was observed in all but one. The erythrocyte sedimentation rate (E.S.R.) repeated three days after the injection of saline solution showed no significant change. Abstracts of the case-histories are given below.

Case 1—A soldier, aged 24, had had painful and swollen wrists and knees for a week. His temperature was 100°F , and pulse rate 100. Twelve hours after injection his temperature dropped to normal and remained so, and his pulse rate to 70. He made an uneventful recovery without further involvement of his joints.

Case 2—A soldier, aged 25, had had, three days previously while in hospital for hernia, polyarticular pain and swelling, temperature 104.2°F , and pulse rate 110. He seemed very ill. Within twenty-four hours of injection all joint pain and swelling had gone, temperature 100°F , pulse rate 100. He still felt ill. After another twelve hours his left knee swelled again and some drowsiness, hyperpnoea, and nausea developed. There was no further rise in temperature or pulse rate.

Case 3—A soldier, aged 27, had had a first attack of rheumatic fever at the age of 12 years, and relapses on several occasions subsequently, generally lasting about three weeks. The present relapse had occurred three days previously. His temperature on admission was 101°F but fell to 100°F , pulse rate 102. Twelve hours after injection his temperature was unchanged, pulse rate 70, and all joint pain and swelling had disappeared. Twelve hours later his pulse rate had dropped to 50.

Case 4—A soldier, aged 23, had had an attack of acute rheumatic fever a week previously. There was some evidence of early carditis. The patient was obviously ill with temperature 103.7°F and pulse rate 112. Twenty-four hours after injection joint pains and swelling very much relieved, temperature remained around 100°F , pulse dropped to 80–90, but the patient still felt ill and started to vomit.

Case 5—A soldier, aged 24, was in tenth day of the fourth attack of rheumatic fever since childhood. He did not feel very ill, but his knees, wrists and ankles were very swollen and painful. His temperature was 102°F , and pulse rate 90. Twenty-four hours after injection his temperature was 99°F and pulse rate 75, the pain and swelling were minimal and there were tingling of extremities and nausea. The patient relapsed to his original condition after cessation of treatment.

Case 6—A soldier, aged 21, was in seventh day of a first attack of rheumatic fever of moderate severity. His temperature was 101°F and pulse-rate 100. Twenty-four hours after injection his temperature was 97°F , and pulse rate 68. From this time he made an uneventful recovery with no further pyrexia or joint swelling.

of the area to be treated. An experienced radiographer will have no difficulty in handling a child.

RESULTS

The total number of cases treated by deep X rays was 41 in a period of twenty seven months. Cases which were followed up for less than five months are not included in this series. The average follow up period was thirteen months. There were 22 male and 19 females. 39 were children from the age of four to thirteen years and the 2 other patients were seventeen and twenty six.

To assess the response we divided our cases into three groups:

- 1 Patients who had hearing loss (deafness)
- 2 Patients with recurrent otitis media with or without suppuration. (This group also included a patient with chronic suppurative otitis media with an anterior perforation due to eustachian infection.)
- 3 Children with frequent colds and nasal obstruction.

Several of the cases belonged to more than one group—e.g., a patient may have recurrent attacks of otitis media with loss of hearing.

Deafness

The response to treatment is assessed (1) symptomatically and clinically, and (2) audiometrically. "Symptomatic and clinical improvement" is judged by the impression of parents or teachers, improvement in school work, and our own observation. The impairment of hearing as shown by audiometer was divided into three degrees:

- 1 Marked: more than 20 decibels
- 2 Slight: under 20 decibels
- 3 No change or worse

To assess the audiometric improvement we took the readings of a corresponding frequency at the point of the greatest loss. The results are shown in table I. In 3 cases audiograms were not taken and in 1 case they were unreliable because the child was too vague. Of these 4, 3 showed considerable symptomatic and clinical improvement.

Fig 1 (case 1)—Audiogram on Sept. 15, 1948

Fig 2 (case 1)—Audiogram on March 30, 1949

Fig 3 (case 2)—Audiogram on Sept. 29, 1948

Fig 4 (case 2)—Audiogram on June 9, 1949

Some of the patients had only slight hearing loss audiometrically and their hearing became normal after treatment. But as the improvement was less than 20 decibels these cases are classified as showing slight improvement.

The following are reports of two cases.

Case 1—Girl aged 10. Had tonsils and adenoids removed when 4 years old. Seen first in June, 1948, because parents noticed deafness. On examination a fairly large tonsillar remnant was present on the right, and slight recurrence of adenoids could be seen. Nasal mucosa congested. Both tympanic membranes pink. Audiogram taken on Sept. 15 showed hearing loss in both ears (fig 1). Radiography of sinuses clear. Deep X ray therapy in October. Audiogram in November showed 10-20 decibels loss in both ears, and in March 1949, the hearing loss was less than 10 decibels (fig 2). Hearing is now normal.

Case 2—Girl aged 6. Had tonsils and adenoids removed in 1947. Seen again in September, 1948, because of recurrent attacks of earache and otorrhea, usually from the right ear, but also from the left. Last attack of acute otitis media in July, 1948. On examination some lymphoid follicles were present on the posterior pharyngeal wall. The right tympanic membrane was retracted and scarred, the left slightly retracted. The Rinne test was negative in both ears. Whispered voice heard from about 2 ft in both ears. An audiogram taken on Sept. 29 showed marked hearing loss in the right ear, in the left ear hearing was moderately reduced (fig 3). X ray therapy was started immediately. An audiogram taken on Jan. 23, 1949, showed only 10 decibels loss in both ears. On June 9, 1949, her audiogram was normal (fig 4). Whispered voice could be heard from 12 ft without difficulty. Rinne was positive. The tympanic membranes were still retracted but there had been no earache or otorrhea since treatment. Improvement has since been maintained.

Recurrent and Chronic Otitis Media

This group (table II) includes 1 case of chronic suppurative otitis media with an anterior perforation which dried up completely after treatment.

Case 3—Boy, aged 9. Had tonsils and adenoids removed at the age of 5 in 1945. Five months later had right acute mastoiditis and operation. Intermittent earache in 1947 and cavity had to be reopened. In March, 1948, he again

had acute otitis media, with pus in scar. Paracentesis and reopening, followed by left acute otitis media. Radiography of sinuses clear. Further attack of right acute otitis media in May with swelling of scar. Deep X ray therapy in June 1948. When seen in April, 1949, he had had no further earache or discharge. The right tympanic membrane was pale and shiny but slightly retracted. Considerable general improvement.

Colds and Nasal Obstruction

In this group (table III) 2 cases had vasomotor rhinitis and showed only slight improvement. The 6 others were treated primarily for deafness or recurrent otitis media, but had colds or nasal obstruction in addition. No conclusions as to the value of the treatment can be drawn, and we doubt whether X ray therapy is indicated unless the case belongs to one of the other two groups as well.

Most workers report almost complete shrinkage of the lymphoid tissue in the nasopharynx and round the eustachian orifices after irradiation. Some of our cases have not shown this diminution, yet their results were satisfactory. In these cases the improvement may have been due to shrinkage of lymphoid tissue inside the eustachian tube, which cannot be detected by clinical examination.

SUMMARY AND CONCLUSION

Over a period of two years, 41 cases with hypertrophy of lymphoid tissue in the nasopharynx have had deep X ray therapy.

The results were encouraging. Final conclusions cannot yet be drawn, but we are convinced that deep X ray therapy has a definite place in the treatment of selected cases of deafness and recurrent otitis media.

We wish to thank Miss M. Adamson, our hospital audiometrist, for the patience shown in testing the patients.

DEHYDRATION TREATMENT OF RHEUMATIC FEVER

W S C COPEMAN

O.B.E., M.A., M.D. Camb., F.R.C.P.

PHYSICIAN TO RHEUMATISM DEPARTMENT, WEST LONDON HOSPITAL

L G C E PUGH

M.A., B.M. Oxon

MEDICAL REGISTRAR, POSTGRADUATE MEDICAL SCHOOL OF LONDON

THE mode of action of salicylates has been investigated by Reid et al. (1950), who suggest that the reduction of fever and tachycardia, together with the relief of pain and swelling in the affected joints during the first five days' therapy, can be attributed to a reduction in the water content of the body cells (dehydration). If similar clinical results were obtainable as the result of cellular dehydration brought about by another method, the basis of this hypothesis would be strengthened.

We treated 7 cases of rheumatic fever by reducing the total water content of the body and following this with a rapid intravenous injection of hypertonic saline solution to displace water from the intracellular to the extracellular fluid compartment of the body. We reported our results (1945) but did not at that time describe them in full.

The effect of this treatment on the patients was clinically comparable with that described by Reid et al.

in their cases treated with large doses of salicylates, and the side effects in our series were also strikingly similar to those which they report.

METHOD

The 7 patients treated were young soldiers serving with the B.L.A. All food and water were withheld from these patients for thirty six hours. Six doses of sodium sulphate $\frac{1}{2}$ oz were administered during this period. The resultant reduction in body water, estimated by loss of body-weight, amounted to 2 or 3 litres. At the end of this period 50 ml of a 30% solution of sodium chloride (15 g) was injected intravenously in about 30 sec. The shift of water from the cells thus produced was calculated to be about 1 litre (Gamble 1942). A cup of tea was allowed during the next four hours to mitigate thirst. The doses of sodium sulphate were continued two hourly for a further twelve hours. Twenty four hours after the injection of sodium chloride, restriction of fluid and food was relaxed.

RESULTS

No clinical effects other than thirst and diarrhoea were observed during the preliminary period of dehydration. Within twenty four hours after the injection of sodium chloride there were relief of pain on movement, reduction of tenderness and swelling of the affected joints, and a fall of temperature and pulse rate. Side effects, such as hyperpnoea, nausea, vomiting, and tingling of the extremities, developed in four cases, and drowsiness was observed in all but one. The erythrocyte sedimentation rate (E.S.R.) repeated three days after the injection of saline solution showed no significant change. Abstracts of the case-histories are given below.

Case 1 — A soldier, aged 24, had had painful and swollen wrists and knees for a week. His temperature was 100°F and pulse rate 100. Twelve hours after injection his temperature dropped to normal and remained so, and his pulse rate to 70. He made an uneventful recovery without further involvement of his joints.

Case 2 — A soldier, aged 25, had had, three days previously while in hospital for hernia, polyarticular pain and swelling, temperature 104.2°F , and pulse rate 110. He seemed very ill. Within twenty four hours of injection all joint pain and swelling had gone, temperature 100°F , pulse rate 100. He still felt ill. After another twelve hours his left knee swelled again and some drowsiness, hyperpnoea, and nausea developed. There was no further rise in temperature or pulse rate.

Case 3 — A soldier, aged 27, had had a first attack of rheumatic fever at the age of 12 years, and relapses on several occasions subsequently, generally lasting about three weeks. The present relapse had occurred three days previously. His temperature on admission was 101°F but fell to 100°F , pulse rate 102. Twelve hours after injection his temperature was unchanged, pulse rate 70 and all joint pain and swelling had disappeared. Twelve hours later his pulse rate had dropped to 50.

Case 4 — A soldier, aged 23, had had an attack of acute rheumatic fever a week previously. There was some evidence of early carditis. The patient was obviously ill, with temperature 103.7°F and pulse rate 112. Twenty four hours after injection joint pains and swelling very much relieved, temperature remained around 100°F , pulse dropped to 80–90, but the patient still felt ill and started to vomit.

Case 5 — A soldier, aged 24, was in tenth day of the fourth attack of rheumatic fever since childhood. He did not feel very ill but his knees, wrists, and ankles were very swollen and painful. His temperature was 102°F , and pulse rate 90. Twenty four hours after injection his temperature was 99°F and pulse rate 75. The pain and swelling were minimal and there were tingling of extremities and nausea. The patient relapsed to his original condition after cessation of treatment.

Case 6 — A soldier, aged 21, was in seventh day of a first attack of rheumatic fever of moderate severity. His temperature was 101°F and pulse rate 100. Twenty four hours after injection his temperature was 97°F , and pulse rate 68. From this time he made an uneventful recovery with no further pyrexia or joint swelling.

Case 7—A soldier, aged 25, was seen on the fourth day of an attack of rheumatic fever of moderate severity. His temperature was 100.8°F, and pulse rate 100. He felt ill, and many joints were very painful and swollen. Twenty-four hours after injection joint pain and swelling had practically subsided, temperature was 98°F, and pulse rate 72. Shortly afterwards the patient developed mild "air hunger," with deep slow sighing respirations and slight nausea. He did not subsequently relapse.

DISCUSSION

The clinical picture observed in these cases is comparable with that described by Reid et al (1950) as developing in their series about the fifth day of massive salicylate therapy. Hyperpnœa, nausea, vomiting, and drowsiness were features of both series of cases, in neither was an early change in ESR found. The chief points in which the two series differ are the intense thirst and tingling of the extremities in our cases, and the well-known tinnitus and deafness of salicylism in the cases of Reid et al.

Although Reid et al attribute the reduction of symptoms to the change in fluid distribution within the body, this phenomenon is but one of several complex changes, and possibly the symptomatic relief may be due to some other, as yet undefined, cause. Similarly the reduction of symptoms in our cases may be due to factors other than the alteration in the volume and distribution of body fluids, such, for instance, as a non-specific stimulation of the adrenal cortex.

No claim is therefore made that the factor of cellular dehydration common to both groups is necessarily the cause of the rapid reduction in symptoms. The object of this note is merely to place on record the similarity of the clinical effects in acute rheumatism treated with massive salicylate therapy and in acute rheumatism treated by dehydration induced more directly by another method.

SUMMARY

Seven cases of rheumatic fever were treated by intracellular dehydration.

The clinical effects were strikingly similar to those reported with massive salicylate therapy.

EFFECTS OF PRISCOL ON THE PERIPHERAL CIRCULATION

R B LYNN

MD Queen's Univ, Ont, F.R.C.S.

From the Surgical Laboratories of the Postgraduate Medical School of London

Of the many chemical compounds recommended for the treatment of peripheral vascular disease few have stood the test of time and critical clinical investigation. 'Priscol' (benzyl imidazoline), one of the more recent vasodilator drugs, has been reported on favourably by Bürklen (1940) and Lindquist (1943) on the Continent, by Grimson et al (1948a and b) in the U.S.A., and by Douthwaite and Finnegan (1950) in this country. Ahlquist et al (1947) and Chess and Yonkman (1946) have shown, in experiments on animals, its sympatholytic and adrenergic actions, its effect on the cardiac output, and its vasodilator action on the limbs, and Winsor and Ottoman (1949) have confirmed its vasodilator action on the limbs in man. The effects of priscol on the peripheral circulation in the limbs of 40 adults are reported here.

METHOD AND RESULTS

The blood flow through the limbs of 30 patients (including 6 normal volunteers) was measured by a

Fig 1—Blood flow in normal person after intravenous injection of priscol 50 mg (In all charts arrow indicates completion of injection)

thermostatically controlled modification of the water filled venous occlusion plethysmograph (Barcroft and Edholm 1945). Fifty limbs were studied by this method.

In the 6 normal volunteers the intravenous injection of priscol 50 mg caused a pronounced increase in blood flow through the hands and feet and only a slight increase in the calf (fig 1). Priscol 50 mg injected into the femoral artery caused a maximal effect in the ipsilateral foot and only a slight increase in the blood flow through the contralateral foot (fig 2). This increase in blood flow was transient but was maintained in all cases above the pre-existing level for the duration of the test but had returned to normal by the next day.

In 3 sympathectomised patients (1 operated on for thromboangitis obliterans, 1 for arteriosclerosis, and 1 for pernio) the intravenous injection of priscol 50 mg caused no appreciable change in blood flow through the feet (fig 3).

In 13 patients with vasospastic disorders of the limbs (Raynaud's disease 3, Raynaud's phenomenon 8, acrocyanosis 1, erythrocyanosis frigida 1) the intravenous injection of priscol caused an immediate increase in the blood flow in both the hands and the feet (fig 4). Ten of these patients received 150 mg of priscol by mouth daily for periods ranging from one to six months, and a definite clinical improvement was noted by both patient and observer in the 3 patients with Raynaud's disease and in 5 of the 8 patients with Raynaud's phenomenon. One of the patients with Raynaud's phenomenon had previously had from one to three attacks of vasospasm every day, but after taking priscol by mouth for a month (March) had only one attack during the period of therapy. One patient with Raynaud's phenomenon secondary to scleroderma, and another with Raynaud's phenomenon secondary to Pott's paraplegia, showed no improvement. Four patients with persistent vasospasm after sympathectomy showed considerable improvement. Of 4 patients with vasospastic disorders whose blood flows were estimated before and after the

administration of priscol by mouth for a month only one showed an increase in blood flow over the pre existing resting level.

In 17 patients with occlusive vascular disease (thrombo angitis obliterans 2, arteriosclerosis 15) the intravenous injection of 50 mg of priscol was followed by an increase in blood flow in the feet (fig 5). In the calf the increase in blood flow was minimal and in some patients it was unchanged. The injection of priscol 50 mg into the femoral artery was followed by an increase in blood-flow in the ipsilateral calf to double the pre existing level, apparently when priscol was given by this method the effect was more sustained (fig 6). Eight patients of this group received priscol 150 mg by mouth daily for a month, and in none of these was there any significant clinical improvement. Claudication distance was not materially improved in any patient. Only grade 2

Fig 2—Blood flow in feet of normal person after injection of priscol 50 mg into right femoral artery

and grade 3 claudicants (Boyd et al 1949) were studied. The calf and foot blood flows were not increased over the pre existing levels in any of these patients.

A patient with an acute embolism of the brachial artery was given 40 mg of priscol by injection into the subclavian artery an hour after the onset of symptoms. The collateral circulation visibly improved immediately, and within two hours the paralysis and anaesthesia had disappeared and the hand was warm, though the radial pulse did not return until next day.

In 3 patients a further degree of vasodilatation was obtained with 50 mg of priscol intravenously at the end of a reflex heating test.

DISCUSSION

It has been found that intravenous priscol is a powerful vasodilator agent which acts particularly on the skin of the extremities. Intra arterial injection of priscol does little more than double the blood flow through the muscle of the calf, and this increase accords with that obtained through muscle by other sympathetic blocking methods (Barcroft et al. 1943). The administration of 150 mg of priscol by mouth daily for a month or more has proved ineffective, judged by plethysmographic criteria. It has been shown that a maximal effect is exerted on the ipsilateral limb when priscol is given by intra arterial injection, and that there is no increase in blood flow in sympathectomised limbs when priscol is given intravenously. It can therefore be concluded that the vasodilatation results from a peripheral sympathetic blocking effect. Its beneficial action

Fig 3—Blood flow in feet of sympathectomised patient after intravenous injection of priscol 50 mg

in vasospastic disorders—particularly in cases which relapse after sympathectomy of the upper limbs—may well be the result of this peripheral effect on regenerated sympathetic nerve fibres. In the blood concentrations obtained with oral dosage it is not likely that the effect of the drug could be a local one on the blood vessels (see Addendum).

The clinical findings recorded here agree fairly well with those of Bürklen (1940), Grimson et al (1948a and b), and Lindquist (1943). Douthwaite and Finnegan (1950) reported improvement in patients with intermittent claudication, but this has not been confirmed in this department. It is suggested that priscol will find its greatest use in vasospastic disorders of the upper limb, and perhaps particularly in cases which relapse after cervicodorsal sympathectomy. Grimson (1950) contends that the immediate and late effects with priscol are as good as those which follow sympathectomy for Raynaud's disease, and some of his cases have now been followed for more than three years. He seldom gives the drug to patients with arteriosclerosis or Buerger's disease, because the results are equivocal. The value of intra arterial priscol in the conservative management of acute arterial embolism needs further confirmation. It is as effective as a paravertebral block (Grimson et al 1948a) and may be used whenever vasodilatation of a limb is desired. Intra arterial injection ensures a maximal effect in the ipsilateral limb, and the blood pressure is not lowered by the dosages used in this study. Priscol may be of value in confirming the completeness of a reflex heating test and in determining suitable candidates for sympathectomy.

Fig 4—Blood flow in patient with Raynaud's phenomenon after intravenous injection of priscol 30 mg

Case 7—A soldier, aged 25, was seen on the fourth day of an attack of rheumatic fever of moderate severity. His temperature was 100.8°F, and pulse rate 100. He felt ill, and many joints were very painful and swollen. Twenty-four hours after injection joint pain and swelling had practically subsided, temperature was 98°F, and pulse rate 72. Shortly afterwards the patient developed mild "air hunger," with deep slow sighing respirations and slight nausea. He did not subsequently relapse.

DISCUSSION

The clinical picture observed in these cases is comparable with that described by Reid et al (1950) as developing in their series about the fifth day of massive salicylate therapy. Hyperpnœa, nausea, vomiting, and drowsiness were features of both series of cases, in neither was an early change in ESR found. The chief points in which the two series differ are the intense thirst and tingling of the extremities in our cases, and the well known tinnitus and deafness of salicylism in the cases of Reid et al.

Although Reid et al attribute the reduction of symptoms to the change in fluid distribution within the body, this phenomenon is but one of several complex changes, and possibly the symptomatic relief may be due to some other, as yet undefined, cause. Similarly the reduction of symptoms in our cases may be due to factors other than the alteration in the volume and distribution of body fluids, such, for instance, as a non-specific stimulation of the adrenal cortex.

No claim is therefore made that the factor of cellular dehydration common to both groups is necessarily the cause of the rapid reduction in symptoms. The object of this note is merely to place on record the similarity of the clinical effects in acute rheumatism treated with massive salicylate therapy and in acute rheumatism treated by dehydration induced more directly by another method.

SUMMARY

Seven cases of rheumatic fever were treated by intracellular dehydration.

The clinical effects were strikingly similar to those reported with massive salicylate therapy.

EFFECTS OF PRISCOL ON THE PERIPHERAL CIRCULATION

R B LYNN

M.D. Queen's Univ., Ont., F.R.C.S.

From the Surgical Laboratories of the Postgraduate Medical School of London

Of the many chemical compounds recommended for the treatment of peripheral vascular disease few have stood the test of time and critical clinical investigation. 'Priscol' (benzyl imidazoline), one of the more recent vaso-dilator drugs, has been reported on favourably by Bürklen (1940) and Lindquist (1943) on the Continent, by Grimson et al (1948a and b) in the U.S.A., and by Douthwaite and Finnegan (1950) in this country. Ahlquist et al (1947) and Chess and Youkman (1946) have shown, in experiments on animals, its sympatholytic and adrenergic actions, its effect on the cardiac output, and its vasodilator action on the limbs, and Winsor and Ottoman (1949) have confirmed its vasodilator action on the limbs in man. The effects of priscol on the peripheral circulation in the limbs of 40 adults are reported here.

METHOD AND RESULTS

The blood flow through the limbs of 30 patients (including 6 normal volunteers) was measured by a

Fig 1—Blood-flow in normal person after intravenous injection of priscol 50 mg (In all charts arrow indicates completion of injection.)

thermostatically controlled modification of the water filled venous occlusion plethysmograph (Barcroft and Edholm 1945). Fifty limbs were studied by this method.

In the 6 normal volunteers the intravenous injection of priscol 50 mg caused a pronounced increase in blood flow through the hands and feet and only a slight increase in the calf (fig 1). Priscol 50 mg injected into the femoral artery caused a maximal effect in the ipsilateral foot and only a slight increase in the blood flow through the contralateral foot (fig 2). This increase in blood flow was transient but was maintained in all cases above the pre-existing level for the duration of the test but had returned to normal by the next day.

In 3 sympathectomised patients (1 operated on for thromboangitis obliterans, 1 for arteriosclerosis, and 1 for pernio) the intravenous injection of priscol 50 mg caused no appreciable change in blood flow through the feet (fig 3).

In 13 patients with vasospastic disorders of the limbs (Raynaud's disease 3, Raynaud's phenomenon 8, acrocyanosis 1, erythrocyanosis frigida 1) the intravenous injection of priscol caused an immediate increase in the blood flow in both the hands and the feet (fig 4). Ten of these patients received 150 mg of priscol by mouth daily for periods ranging from one to six months, and a definite clinical improvement was noted by both patient and observer in the 3 patients with Raynaud's disease and in 5 of the 8 patients with Raynaud's phenomenon. One of the patients with Raynaud's phenomenon had previously had from one to three attacks of vasospasm every day, but after taking priscol by mouth for 1 month (March) had only one attack during the period of therapy. One patient with Raynaud's phenomenon secondary to scleroderma, and another with Raynaud's phenomenon secondary to Pott's paraplegia, showed no improvement. Four patients with persistent vasospasm after sympathectomy showed considerable improvement. Of 4 patients with vasospastic disorders whose blood flows were estimated before and after the

Standard curve used in estimating adrenocorticotrophic activity of blood plasma. Each plotting point represents the mean of the findings in six rats.

Rats weighing about 150 g were hypophysectomised by the parapharyngeal approach under light ether anaesthesia. Twenty four hours later they were anaesthetised with pento barbitone sodium, 4 mg per 100 g of body weight, and the left suprarenal was removed from each rat for analysis. 0.5 ml of the final extract was then given intravenously into a tail vein, and an hour later the right suprarenal was removed from each rat and prepared for analysis. The amount of ascorbic acid was estimated by the technique of Roe and Kuether (1943).

The difference in content of ascorbic acid between the left and right suprarenals is regarded as the index of the adrenocorticotrophic activity of the extract of blood plasma (see figure).

The reference standard, in which the results are expressed, is a sample of beef A C T H prepared in this laboratory according to the technique of Fishman (1947) in which the initial extraction procedure is identical with that used in preparing the plasma extract.

MATERIAL

The subjects investigated were 12 normal people aged 17-61, 3 patients with Cushing's syndrome, 1 patient with panhypopituitarism, 1 patient with Simmonds's disease, 6 patients with severe congestive failure (both while in acute failure and under control), 2 women with simple hirsutes, 3 postoperative patients, and 6 patients with uncontrolled diabetes mellitus but with no evidence of ketosis.

All 3 cases of Cushing's syndrome presented with similar characteristics—namely, rapidly increasing obesity, moderate hirsutes, and amenorrhoea.

Case 13 showed gross obesity with pigmented striae confined to the abdomen and lower thorax, blood pressure 180/110 mm Hg, moderate hair growth on the upper lips, glycosuria, pubic hair of masculine distribution, and atrophic external genitalia.

Case 14 showed moderate obesity somewhat more generalised but principally abdominal with pigmented striae, blood pressure 170/110 mm Hg, intermittent glycosuria, hirsutes of face and thorax, pubic hair of masculine distribution and atrophic external genitalia.

Case 15 showed well marked abdominal obesity, with pigmented striae, blood pressure 150/110 mm. Hg, no facial hirsutes, pubic hair of masculine distribution and atrophic external genitalia.

The biochemical findings are summarised in table I.

Case 16 (Simmonds's disease)—Two years before admission she had had a very difficult labour with severe postpartum haemorrhage necessitating repeated transfusions. After it lactation did not come on, amenorrhoea persisted, and the axillary and pubic hair and eyebrows disappeared. She was a slow speaking and somewhat mentally retarded young woman with a tendency to obesity, no eyebrows and no axillary or pubic hair, and gross atrophy of external genitalia.

The results are expressed in table I and a statistical survey is given in table II.

DISCUSSION

Assay

The assay technique, as described, is subject to certain criticisms. First, as fractionation was not carried through to the "pure" hormone stage, we cannot state that the extract contains no substance other than A C T H. Secondly, it must be emphasised that the values obtained do not necessarily represent true amounts of A C T H per 100 ml of plasma but merely activity in terms of a particular standard. This statement is further strengthened by the work of Li (1950) and others who have shown that hydrolysis of the so called "pure hormone"

Comparison of A C T like activity of the various groups investigated shows that

For A and B	n = 13	T = 7.21	P is < 0.001
A and F (I)	n = 16	T = 10.75	P is < 0.001
A and F (II)	n = 15	T = 0.264	P is 0.8
A and G	n = 13	T = 5.59	P is < 0.001
A and H	n = 16	T = 0.270	P is 0.8
F (I) and F (II)	n = 4	T = 12.22	P is < 0.001

T represents the variance of the means and P the probability of the results being due to chance. Values of P of 0.01 or less are regarded as significant.

Fig 5—Blood flow in feet of patients with mild, moderate, and advanced arteriosclerosis after intravenous injection of priscol 50 mg

followed by facial flushing, suffusion of the face, palpitations, and a feeling of fullness in the head. These symptoms passed off in about 10 minutes, but the blush was apparent for much longer. In most cases there was a mild transient tachycardia. In the dosage used in this study no appreciable effect on the blood pressure was noted. Various

Fig 6—Blood flow in ipsilateral calf in patient with arteriosclerosis after injection of priscol 50 mg into femoral artery

“goose flesh” and shivering were encountered after intravenous injection was not followed by any ill effects.

SUMMARY

Effects of priscol administered by mouth, intravenously, and intra arterially have been studied in patients with arteriosclerosis. Clinical criteria and venous occlusion plethysmography were used for the assessment of

the effect of a peripheral sympathetic blocking agent, and its greatest effect on the hands and feet. It had a marked effect on the calf.

The value in the treatment of vasospastic disease is unlikely that it will improve patients with peripheral vascular disease.

The use of priscol in the treatment of acute arterial disease needs further confirmation.

The use of priscol in the determination of suitability for sympathectomy.

Priscol was well tolerated in therapeutic doses and was provided by Ciba Laboratories Ltd.

ADDENDUM

This paper was submitted for publication, to the Medical Research Council, at the Sherrington School of Physiology, St Thomas's Hospital, has shown that the intravenous injection of 50 mg of priscol into the brachial artery causes an immediate and pronounced increase in blood flow in the sympathectomised hand. This has been confirmed in the sympathectomised foot. The injection of 50 mg of priscol into the brachial artery increases the blood flow in the foot four times its previous value. This finding indicates that priscol, besides being a sympathetic blocking agent, has a direct local action on the blood

vessels when delivered to them in a sufficiently high concentration.

ADRENOCORTICOTROPIC ACTIVITY OF BLOOD-PLASMA EXTRACTS

J BORNSTEIN*

PHYLLIS TREWHELLA*

M.D. Melbourne, M.R.A.C.P.

B.Sc. Melbourne

From the Baker Medical Research Institute, Alfred Hospital, Melbourne

THE experiments of Conn and his group (1949, 1949), in which temporary diabetes mellitus was induced in human volunteers by the administration of pituitary adrenocorticotrophic hormone (A.C.T.H.), made it desirable to ascertain whether this substance was present in excess in the blood of patients with diabetes mellitus.

The possibility of such an assay was first shown when Sayers et al (1948) assayed A.C.T.H. by the decrease in amount of suprarenal ascorbic acid in hypophysectomised rats. Cooke et al (1948) showed that acetone fractionated blood plasma would produce such a decrease.

Taylor et al (1949), reviewing the literature, considered that all the methods used before that of Cooke et al (1948) were inconclusive. Using unfractionated blood plasma they found no activity in plasma obtained from normal persons but they demonstrated activity in plasma obtained from patients with Cushing's syndrome or Addison's disease, and patients under postoperative stress.

The discrepancy between the results obtained by Cooke et al (1948) and Taylor et al (1949) suggested to us that fractionation of the plasma was necessary.

The method finally chosen is a modification of the technique used by Lyons (1937) to obtain crude 'Pro-lactin,' which contains A.C.T.H. from the anterior pituitary glands.

METHOD

Preparation of Extract

10 ml of blood was taken from the subject into a heparinised syringe and immediately centrifuged. The plasma was taken off and added to 4 volumes of acid acetone, prepared by adding 25 ml of analytically pure hydrochloric acid to 975 ml of redistilled acetone. The resulting precipitate was allowed to stand at room temperature for eight hours, being vigorously shaken at intervals, and then centrifuged. The supernatant fluid was taken off, 1 ml of saturated sodium chloride solution was added, and the concentration of acetone was brought to 94%. The mixture was agitated and allowed to precipitate at 4°C for twelve hours.

The resulting precipitate was centrifuged and the supernatant fluid discarded. The final residue was washed with acetone and dried in a desiccator.

From 6 ml of plasma containing roughly 300–420 mg of total proteins about 4–8 mg of final precipitate was obtained. This precipitate was dissolved in 2.5 ml of distilled water.

Assay

The assay was carried out according to the classical method of Sayers et al (1948). The consistency of the results is much improved if, after preliminary narcotisation with pentobarbitone sodium, ether anaesthesia is used.

* Working under a full time grant from the National Health and Medical Research Council (Commonwealth of Australia).

Standard curve used in estimating adrenocorticotrophic activity of blood-plasma. Each plotting point represents the mean of the findings in six rats

Rats weighing about 150 g were hypophysectomised by the parapharyngeal approach under light ether anaesthesia. Twenty-four hours later they were anaesthetised with pento-barbitone sodium, 4 mg per 100 g of body weight, and the left suprarenal was removed from each rat for analysis. 0.5 ml of the final extract was then given intravenously into a tail vein and an hour later the right suprarenal was removed from each rat and prepared for analysis. The amount of ascorbic acid was estimated by the technique of Roe and Kuether (1943).

The difference in content of ascorbic acid between the left and right suprarenals is regarded as the index of the adrenocorticotrophic activity of the extract of blood plasma (see figure).

The reference standard, in which the results are expressed is a sample of beef ACTH prepared in this laboratory according to the technique of Fishman (1947) in which the initial extraction procedure is identical with that used in preparing the plasma extract.

MATERIAL

The subjects investigated were 12 normal people aged 17-61, 3 patients with Cushing's syndrome, 1 patient with panhypopituitarism, 1 patient with Simmonds's disease, 6 patients with severe congestive failure (both while in acute failure and under control), 2 women with simple hirsuties, 3 postoperative patients and 6 patients with uncontrolled diabetes mellitus but with no evidence of ketosis.

All 3 cases of Cushing's syndrome presented with similar characteristics—namely, rapidly increasing obesity, moderate hirsuties, and amenorrhoea.

Case 13 showed gross obesity, with pigmented striae confined to the abdomen and lower thorax, blood pressure 180/110 mm Hg, moderate hair growth on the upper lips, glycosuria, pubic hair of masculine distribution, and atrophic external genitalia.

Case 14 showed moderate obesity somewhat more generalised but principally abdominal with pigmented striae, blood pressure 170/110 mm Hg, intermittent glycosuria, hirsuties of face and thorax, pubic hair of masculine distribution and atrophic external genitalia.

Case 15 showed well marked abdominal obesity, with pigmented striae, blood pressure 150/110 mm Hg, no facial hirsuties, pubic hair of masculine distribution and atrophic external genitalia.

The biochemical findings are summarised in table I.

Case 16 (Simmonds's disease)—Two years before admission she had had a very difficult labour with severe postpartum haemorrhage necessitating repeated transfusions. After it lacted did not come on, amenorrhoea persisted and the axillary and pubic hair and eyebrows disappeared. She was a slow speaking and somewhat mentally retarded young woman with a tendency to obesity, no eyebrows and no axillary or pubic hair and gross atrophy of external genitalia.

The results are expressed in table I and a statistical survey is given in table II.

DISCUSSION

Assay

The assay technique, as described, is subject to certain criticisms. First, as fractionation was not carried through to the "pure" hormone stage, we cannot state that the extract contains no substance other than ACTH. Secondly, it must be emphasised that the values obtained do not necessarily represent true amounts of ACTH per 100 ml of plasma but merely activity in terms of a particular standard. This statement is further strengthened by the work of Li (1950) and others who have shown that hydrolysis of the so called "pure hormone"

† Estimated by method of Venning et al (1942)

Comparison of ACT like activity of the various groups investigated shows that

For A and B	n = 13	T = 7.21	P is < 0.001
A and F (i)	n = 16	T = 10.75	P is < 0.001
A and F (ii)	n = 15	T = 0.264	P is 0.8
A and G	n = 13	T = 5.59	P is < 0.001
A and H	n = 16	T = 0.270	P is 0.8
F (i) and F (ii)	n = 4	T = 12.22	P is < 0.001

T represents the variance of the means and P the probability of the results being due to chance. Values of P of 0.01 or less are regarded as significant.

yields polypeptides whose activity is, weight for weight, about eight times that of the protein hormone

However, as a result of our study of abnormal states in which the concentration of A C T H may be expected to vary, a striking parallelism has appeared between the activity of the plasma extracts as estimated by our technique and the excretion of 11 glucosteroids. As it has been shown by many workers that the injection of A C T H leads to the excretion of excess 11 glucosteroids, we consider that the assays at least give a representation of the adrenocorticotrophic activity of the blood plasma, though we do not suggest that the figures obtained represent true weights of A C T H

20 (i)	20 (ii)	4.54	<0.01
21 (i)	21 (ii)	4.96	<0.01
23 (i)	23 (ii)	4.44	<0.01
24 (i)	24 (ii)	5.10	<0.01
25 (i)	25 (ii)	2.02	<0.05 >0.02

Consideration of these results shows that there is a significant alteration of ascorbic acid depletion in Cushing's syndrome and Simmonds's disease but that the alterations in congestive failure and postoperative states can only be regarded as suggestive. However the comparison between the same cardiac patients while in failure and after recovery shows a significant alteration in all cases

It may be said that the values of activity in terms of the standard appear extremely high, but in this respect it is pointed out that, when A C T H is used therapeutically 10-25 mg has to be given in one injection to produce a maximal effect, and this dose is equivalent to 330-830 µg per 100 ml of plasma

Conditions Investigated

The results found in Cushing's syndrome show that in the 3 cases investigated the primary disorder seems to be a form of hyperpituitarism acting through the suprarenals

The result obtained in Simmonds's disease is what one would expect in this condition, since it is assumed that the pituitary has been destroyed

The results obtained in hirsuties in females, showing no metabolic or sex upset, although somewhat raised are only slightly above the upper limit of the normals, and we think them of doubtful significance

Similar considerations apply to the case of hypopituitarism, where only a small diminution in the activity of the extract was found

The results obtained in the postoperation cases demonstrate that, in the presence of stress, there is an increase in corticotrophic activity which is in keeping with the well known finding that excretion of 11 glucosteroids is increased considerably after operations

The finding of normal values in uncontrolled diabetes mellitus without ketosis is in keeping with the findings of McArthur et al (1950) that excretion of steroids was normal in diabetes mellitus except in the presence of ketosis, when it was increased

The results generally suggest that the diabetic state produced by Conn et al (1948-1949) resembles that found in the Cushing syndrome

The most significant findings are those obtained in cardiac failure, where blood obtained from the distressed dyspnoeic cardiac patient has a raised adrenocorticotrophic activity, which subsides to normal on recovery of the patient to a more normal general state. Though we regard this as merely another example of response to stress, the work of Conn and Lous (1950) on the salt content of sweat suggests that in these circumstances excess adrenocorticotrophic activity may lead to retention of sodium and thus maintain a vicious circle

SUMMARY

A technique for the assay of adrenocorticotrophic activity of human blood plasma is described

Increased activity was found in Cushing's syndrome, postoperative stress, and congestive heart failure. Greatly reduced activity was found in Simmonds's disease. Normal activity was found in uncontrolled diabetes mellitus without ketosis

We wish to thank Dr Ewen Downie, Dr T E Lowe, Dr H B Kay, and Mr G Grove, of the Alfred Hospital, for permission to study cases under their care, and Miss M Bick, senior biochemist of the hospital, for the 17 ketosteroid estimations

RELAPSE OF KALA-AZAR AFTER SPLENECTOMY

A DAS

M.B. Calcutta, M.R.C.P.

PROFESSOR OF CLINICAL MEDICINE
MEDICAL COLLEGE, CALCUTTA

P C SEN GUPTA

M.B. Calcutta

OFFICER I C KALA-AZAR RESEARCH DEPARTMENT,
SCHOOL OF TROPICAL MEDICINE, CALCUTTA

SEVERAL reports have been published during the last few years indicating that splenectomy may be successful in curing drug resistant kala azar. Morton and Cooke (1948) reviewed the literature on the subject and reported three cases, one a previously untreated case and two drug resistant cases, that were cured of kala azar after splenectomy preceded and/or followed by specific treatment. They concluded that splenectomy should be considered in selected drug resistant cases of kala azar and the operation followed by further courses of chemotherapy. Murgatroyd (1949) also reported the immediate success of splenectomy in a case of drug resistant kala-azar. Napier (1949), reviewing the paper of Morton and Cooke, reported that one of the drug resistant cases reported by them relapsed later. We present here a case of drug-resistant kala azar that relapsed after splenectomy.

CASE RECORD

An Indian aged 25, was admitted to the Medical College Hospital Calcutta on Oct 2 1948. He had first suffered from enteric like fever for three weeks about the end of 1940. After an apyrexial period of two months he had relapse of fever with bleeding from the gums and splenic enlargement. He was then diagnosed as a case of kala azar and was treated with injections of urea stibamine. He was in good health for three months, then he had a relapse which was treated with sodium antimony gluconate, and he was relieved of his symptoms. During 1942 and 1943 he had no significant fever. During the latter part of 1943 he had a relapse with jaundice and firm splenomegaly. After protracted treatment by various methods he partially responded to antimonials. A subsequent relapse occurred in 1947, and he was admitted to a hospital with pyrexia enlargement of the liver, and massive splenomegaly. A blood-count showed anaemia and leucopenia with a decrease in the number of granulocytes. The aldehyde test was positive and the antimony test strongly positive. In spite of treatment with sodium antimony gluconate the spleen remained massive and the patient was suspected of having splenic anaemia. In 1947 he was transferred to another hospital for splenectomy (November, 1947), after which he was in good health for about four months. Then the present attack of fever commenced. The fever was mainly intermittent and often associated with chill and rigor and occasionally there was bleeding from the gums. Several of his family had had kala azar.

On admission the patient was thin and anæmic. The gums were spongy and bled on slight pressure. There was a splenectomy scar on the left paramedian line over the abdomen. The liver was firm slightly tender, and enlarged to four finger breadths below the costal margin. A blood-count showed anaemia (Hb 8 g per 100 ml.) and slight leucopenia (white cells 4500 per c.mm.) and platelets 234,000 per c.mm. The aldehyde test and the complement-fixation test for kala azar were positive and numerous Leishman Donovan bodies were found in the sternal puncture smear. The urine and the faeces did not show any abnormality. A radiograph of the chest was normal.

Treatment and Progress.—The patient was treated with urea stibamine, 2.75 g being given in sixteen injections between Nov. 9 and Dec. 20 1948. During the course of injections he had severe hæmorrhages from the gums, and this led to interruption of specific treatment. The hæmorrhage did not respond to the usual antihæmorrhagic drugs, but the bleeding subsided each time after penicillin injections. During this period a painful swelling developed over the right tibia.

radiography showed a small area of necrosis on the upper posterior part of the tibia. The appearances were not those of scorbutic changes.

At the conclusion of the injections of urea stibamine the patient did not become completely afebrile. Occasional attacks of low intermittent pyrexia persisted. But he felt better and gained 2 lb in weight. A blood count done a month after the completion of specific treatment showed Hb 9.28 g per 100 ml, red cells 3,140,000 per c.mm. (reticulocytes 1.6%), mean corpuscular volume 98.7 c μ , mean corpuscular Hb 29.5 μ g, mean corpuscular Hb concentration 29.9%, white cells 10,200 per c.mm. (neutrophils 55%, lymphocytes 28%, monocytes 8%, eosinophils 9%), platelets 504,000 per c.mm., and prothrombin time 30 sec. A sternal puncture smear on Jan. 24 1949, showed leishmania. The marrow was cellular and showed normoblastic reaction. It was therefore apparent that, in spite of the considerable increase in the number of leucocytes and platelets, the patient was not cured of kala azar.

About the first week of February 1949, the patient developed slight ascites. He was next put on a course of pentamidine, 0.75 g being given in eight injections on consecutive days. But there was an increase of fever and recurrence of bleeding from the gums. Pentamidine had to be withheld because of high fever and the onset of other complications.

On Feb. 23, 1949, the patient showed signs of pleural effusion on the left side and on March 2 1949 on the right side as well. Exploratory puncture produced straw-coloured fluid containing total protein 6.5 g per 100 ml, albumin 3.8 g per 100 ml, globulin 2.7 g per 100 ml.

The patient steadily went downhill in spite of symptomatic treatment and the high remittent fever persisted. He died on March 10 1949. Necropsy was refused.

DISCUSSION

This patient had the first attack of kala azar with enteric like onset about the end of 1940. Kala-azar was diagnosed, and the patient was treated with urea stibamine in 1941, but he relapsed about three months later. The subsequent history is essentially one of relapses of kala azar at various intervals and of occasional antimony therapy, with increasing splenomegaly and the onset of various complications with the passage of time. Unsatisfactory response to antimony apparently led to the diagnosis of splenic anaemia and ultimately to splenectomy. The patient was in good health for only four months after splenectomy and then he had the next relapse. The treatment of this relapse of kala azar with urea stibamine was not successful in eradicating the infection, the parasites persisted in the sternal puncture smear a month after the completion of the course of injections of urea stibamine. The patient was next being treated with pentamidine, when he developed high fever and polyserositis and died.

The other clinical features of interest were the severe hæmorrhages from the gums that apparently responded satisfactorily to penicillin and not to antihæmorrhagic drugs, the necrosis of bone and the polyserositis a rare complication of kala azar.

The results obtained by different workers with splenectomy in the treatment of kala azar are as follows:

TABLE II—RELATION OF CYTOLOGICAL CHANGES TO INITIAL CELL-COUNT—

Initial cell count (per c mm)	No of cases	Average cell count		
		Spec 2	Spec 3	Spec. 4
0-1	43	5	8	22
2-4	17	8	16	34
5-10	8	17	26	53

was observed. The chlorides were examined in 18 cases and showed an alteration of more than 3 mg per 100 ml in 4 cases only. The sugar was estimated in 23 cases, but an alteration of more than 3 mg per 100 ml was observed in no more than 2 cases. The protein was estimated in 57 cases, and, a change of 3 mg per 100 ml being again taken as the smallest significant change, there was a fall in 24 cases, no change in 23, and a rise in 10. In 2 cases the rise was considerable (27 mg and 49 mg per 100 ml), and both these were cases of post-traumatic external hydrocephalus—the only possible correlation with diagnosis that was discovered.

PREVIOUS WORK

Neither Luckett (1913) nor Dandy (1918, 1919) mentioned any changes in the CSF, and the first recorded study after pneumo encephalography is that of Hermann (1922), who, like several later workers (Weigeldt 1922, von Thurzo and Nagy 1923, Cestan and Riser 1924, Friedman et al 1928, Jacobi 1930, Grant 1932, Eley and Vogt 1932, Krypsin Exner 1932, Liberson 1933, von Storch 1936, Newman 1937, Levinson et al 1939), concentrated his observations on the very different and more dramatic changes which occur in the hours following pneumo encephalography.

Tschugunoff (1920) found, in 10 cases, a mononuclear pleocytosis at the end of the procedure, and Conwell (1930) observed such a rise during its course, similar findings being reported by Lund and Neel (1941) in 38 mental patients.

The most important study, however, is that of Schwab and von Storch (1937), who compared the cytological changes during and after pneumo encephalography, using the method of alternate replacement on 14 patients and simultaneous replacement on 10. They state "Differential counts on 13 samples of CSF demonstrated a rise of more than 75% polymorphonuclear cells in all earlier samples." The changes were less with the simultaneous method.

DISCUSSION OF PLEOCYTOSIS

It therefore seems that a rise in the mononuclear cell count is always to be expected during pneumo encephalography, that the degree of rise is very variable, and that it depends only on the number of cells initially present. It follows that samples of CSF taken during pneumo encephalography are in no way representative of the normal cytology of the CSF.

The constancy of this rise is at variance with the findings of Alajouanine et al (1948), who attached diagnostic significance to the cell count found after the introduction of 40 c cm of air, but it is not clear how long afterwards the second samples were analysed. Nor do the present findings support the statement by Schwab and von Storch (1937) that there is a 75% polymorph response in the earlier specimens.

As regards the mechanism of these changes, it seems that several possible explanations can be offered for the rise in the cell count: (1) the changes are the result of the withdrawal of large amounts of CSF, (2) they are due to the irritant effect of the air, (3) they are associated with the alternate lowering and raising of the intrathecal pressure, or (4) they are due to a combination of the above.

Removal of Fluid

If this alone were responsible, simple thecal drainage done with similar apparatus, similar quantities of fluid, and over a similar time as in pneumo encephalography should produce a progressive rise in cell count. This manoeuvre is now only occasionally done, for it is necessary to remove at least 35-40 ml of CSF before one has a comparable situation.

In 2 cases of sagittal sinus thrombosis and 3 of post-traumatic headaches 40 ml of CSF was removed by this method, and, though the figures were originally only small, there was in each case a progressive fall in cell count. This is not unexpected, when one considers that one is draining the cerebral sub-arachnoid spaces and ventricles, where the cell count is normally lower than in the lumbar CSF. This was confirmed to some extent in a case where a pneumo encephalography was done for the second time 8 days after the first. The initial sample of CSF was still abnormal (containing 30 mononuclear cells per c mm), and, whereas we have seen that high initial samples are usually accompanied by high final counts, in this case there was a steady fall throughout. It was then discovered that owing to faulty apparatus no air had entered the thecal space and a simple thecal drainage had been done.

Though Masserman (1934) and Riser and Planques (1936), investigating protracted drainage of CSF, found that a pleocytosis developed, this did not manifest itself until several hours after the start of drainage, whereas it has been shown here that during pneumo encephalography the pleocytosis is usually evident within the first 10 minutes. It therefore seems that simple removal of CSF cannot be responsible.

Irritant Effect of Air

On casual thought this seems to be the most likely explanation, but it is doubtful if it will survive closer examination. It is, for example, difficult to believe that a substance with such mildly irritating properties as air can, within so very short a time, produce so great a rise in cell count. In 50 cases a definite, and sometimes considerable, rise had appeared in specimen 2 (and therefore within 10 minutes). In one case the count had risen from 7 to 34 cells per c mm in 10 minutes, in another from 1 to 18 cells per c mm in 3 minutes, and in a third from 1 to 13 cells per c mm in 2 minutes, and there are many examples of smaller, but still significant, changes which have developed in a very short time. If this is to be attributed to the irritation of the meninges by air, it is obviously a very acute process. One would therefore expect to find an outpouring of polymorphs, but these begin to appear only towards the end of the longer procedures, and often (43 cases) do not appear at all.

That the air plays the rôle of an irritant at a later period is undoubted, for all specimens examined several hours afterwards showed a high polymorph reaction, but, when the reaction develops during pneumo encephalography, one is forced to conclude either that the earliest response to meningeal irritation is a mononuclear response, or that some other mechanism is responsible.

The mononuclear response during pneumo encephalography is perhaps emphasised in those patients examined after some other procedure in which the meninges have been irritated—e.g. ventriculography, or blood contamination during lumbar puncture. One such patient, examined five days after a ventriculography in which the fluid was also slightly contaminated by blood, gave the following figures:

	Total cells	Cells per c mm Polymorphs	Mononuclears
Initial specimen	26	15	11
After 25 ml (7 minutes)	40	15	25
After 75 ml (35 minutes)	63	19	44

Exactly the same type of response was found in 3 other similar cases

During the present investigation, with the cooperation of the neurosurgical department, a few specimens of c s f were examined during ventriculography—the first on initially tapping the ventricles, and the second about 20–30 minutes after the introduction of 20–25 c cm of air. No rise in the cell count was demonstrated, yet examination next day, or several days later, showed that a polymorph response had eventually taken place.

It seems that, though the irritant effect of the air may show itself several hours after pneumo encephalography, this alone is not responsible for a significant increase in cell count during the early minutes of the operation.

Alternate Raising and Lowering of Intrathecal Pressure

However carefully one regulates the withdrawal of c s f and introduction of air when using the alternate replacement method, a swing from negative to positive pressure within the thecal space is bound to happen often, when small quantities of c s f (5 ml.) are replaced at one time.

Von Storch (1936) and Schwab and von Storch (1937) found a much smaller rise with their simultaneous replacement method, and believed that the alternate method produced a form of "cerebral massage" with alternate dilatation and constriction of cerebral and meningeal arterioles, hyperemia, cerebral oedema, and exudation of cells. If this is so, withdrawal and reinjection of c s f alone without air being introduced, should have a similar result. That this does happen has been shown by Masserman (1934), who found that by repeated drainage and reinjection of c s f counts as high as 3600 cells per c mm could be obtained, and he notes that "alternate reduction and increase in pressure can of itself produce pleocytosis."

Levinson et al. (1939) also believed that the permeability of the meningeal and cerebral vessels was increased, and thus forms the theoretical basis of "spinal pumping," introduced by Speransky (1936), whose procedure is essentially comparable to that of pneumo-encephalography, except that the c s f is reintroduced and no air is allowed to enter. Speransky thought that there is a considerable increase in the permeability of the blood brain barrier, and claimed remarkable cures of an amazing variety of diseases. He and his co-workers do not record any examination of the cell count in the c s f in man but they mention that in dogs the c s f became turbid, next yellow, and finally frankly bloodstained.

The work that has been done on this method in recent years has been mainly in the treatment of rheumatoid arthritis (Gillman and Gillman 1946, Savage 1948), but no mention is made of cytological examination.

Personal observations have been made, however, in 3 cases where the conditions of pneumo-encephalography were reproduced but each portion of fluid withdrawn was reinjected, with great care to allow no air to enter. In 2 cases the cell count was unchanged, and in the 3rd it rose 1 cell to 3 cells per c mm only. In these cases the "cerebral massage" was not accompanied by extensive withdrawal of fluid as in Masserman's work.

Combination of Factors

From what has already been said it seems unlikely that the mere withdrawal of c s f plays any part in this phenomenon but the combination of such withdrawal with the mechanical "massage" is important. The fact that Schwab and von Storch (1937) still found changes though much smaller, when using the simultaneous technique suggests that, if the apparatus was efficient, the air or its movement through the c s f plays some part, and Kamihara et al. (1932)

found, in dogs, that the introduction of very small amounts of air (0.5–1.0 c cm) tended to produce a lymphocytic response about an hour afterwards, whereas larger amounts led to a polymorph pleocytosis. It may therefore be incorrect to exclude any direct effect of the air in the early stages.

BIOCHEMICAL CHANGES

The only frequent biochemical change was a decrease in the protein content, probably due to dilution of lumbar c s f with that from the intracranial cisterns. Previous observers have reported an increase in sugar (Schwab and von Storch 1937, Levinson et al. 1939), and Bradley (1937) and Delay and Soulaiaac (1944) have shown a hyperglycaemia towards the end of and after encephalography, and it would not be difficult to understand, if meningeal vascular permeability is increased, how a rise in the c s f sugar level might parallel that in the blood.

The changes which take place hours and days after pneumo encephalography present a very different picture. These are being studied in detail and will be reported later, for they are on occasion the cause of considerable alarm both to patient and attendant, are not infrequently misinterpreted, and may be the reason for unnecessary intrathecal medication.

SUMMARY

The changes in cytology and biochemistry of the cerebrospinal fluid in the course of pneumo encephalography have been studied in 68 cases.

The cell count rose in 66 cases, starting within ten minutes in 50 cases, and reaching figures between 30 and 92 cells per c mm in the final specimen in 22.

Mononuclear cells were almost exclusively involved, the polymorphs appearing in very small numbers at the end of the operation in 25 cases only.

The level of the initial cell count was the only factor influencing the response.

Biochemical changes were slight and of little significance.

Possible explanations for the changes are discussed.

The major credit for the results of this investigation goes to the staffs of the departments of clinical pathology and biochemistry, United Birmingham Hospitals, under the direction of Dr A. L. Peeney and Dr Garfield Thomas respectively. I wish also to thank the house physicians to the neurological unit who successively gave great assistance with the pneumo-encephalographies, and Prof P. C. P. Cloake and Dr G. S. Hall, on whose patients the great majority of these investigations were made.

ROYAL SOCIETY OF MEDICINE

Symmetrical Cortical Necrosis of the Kidney

At a meeting of the section of obstetrics on Nov 17, with Mr V B GREEN ARMYTAGE, president of the section, in the chair, a discussion on symmetrical cortical necrosis of the kidney was opened by Prof H L SHEEHAN.

He described the pathological findings in the kidney at various times after concealed accidental hæmorrhage. He attributed cortical necrosis and other less severe renal lesions to angiospasm occurring approximately coincidentally with the intra uterine hæmorrhage. Evidence of parenchymal damage or death, and necrosis and thrombosis of arteries, appears when the spasm relaxes and blood flows into the damaged area. The severity of the histological changes are correlated with the extent and duration of the antecedent angiospasm, and these changes may be classified into nine types.

Type-1 lesions result from spasm of the afferent glomerular arteriole lasting 15-30 minutes, there is subsequent albuminuria and occasionally some cast formation in collecting tubules. The kidney usually returns to normal in 1-2 days.

Type-2 lesions follow afferent arteriolar spasm lasting about 1 hour. Hyaline droplet formation or colloid degeneration of the proximal convoluted tubules progresses between 6 and 24 hours after the uterine hæmorrhage, but these changes disappear in the next 2 or 3 days. Colloid casts may develop in the tubules of the intermediate zone and lead to more serious impairment of renal function.

Type-3 lesions follow afferent arteriolar spasm lasting 2-3 hours. The proximal tubule cells are killed, but are histologically unaltered until the blood flow returns, when they become necrotic. The lesions are maximal after 24 hours. Signs of regeneration appear after 3 days, and the tubules are relined with flattened epithelium after 6 days, this may atrophy later. Extensive tubular necrosis produces great oliguria for a week or more and may lead to death.

Type-4 lesions—"benign thrombosis of glomeruli"—follow 4-5 hours' arteriolar spasm with subsequent relaxation. Thrombi lie freely in the centre of the glomerular capillaries. The cortex otherwise shows a type-3 lesion.

Type-5—"focal cortical necrosis"—is characterised by stasis or thrombosis of occasional glomerular tufts and afferent arterioles which have been killed by focal spasm in these arterioles lasting 8-10 hours. These lesions develop at about 12-14 hours. A few small foci of cortical necrosis result. As with all other types of cortical necrosis, the remaining parenchyma is extensively involved by the type-3 lesion.

In *type-6*—"minor cortical necrosis"—the spasm begins in afferent arterioles but later involves the distal segments of interlobular arteries where it lasts 8-10 hours. The distal part of the arterial tree, and the glomeruli and tubules supplied by the affected artery, die. Arterial necrotic lesions and thrombosis occur when the spasm relaxes.

In *type-7*—"patchy cortical necrosis"—the spasm begins in afferent arterioles but subsequently moves back to many of the intralobular arteries at about mid-cortex. It lasts about 15-18 hours. When the spasm relaxes there is a characteristic arterial thrombosis. The prognosis is very poor as so much of the cortex is destroyed.

Type-8 lesions—"gross cortical necrosis"—result from an initial afferent arteriole spasm which later passes back to involve the interlobular artery distal to the origin of the afferent arterioles of the basal glomeruli. The spasm lasts about 24 hours and produces death of most of the cortex. When it relaxes, thrombosis occurs in the dead arteries. This condition is always fatal, usually within 7-10 days.

Type-9 lesions—a less common variant of "gross cortical necrosis"—are due to the arterial spasm lasting 2-3 days. An occlusive thrombus forms at the proximal

extremity of the affected arterial segment, and there are no lesions referable to the passage of blood into the damaged area.

Dr A M JOEKES, together with Dr G M BULL and Dr K C LOWE, has studied 120 cases of anuria or low specific gravity oliguria, in 10 of which there was a possible diagnosis of cortical necrosis. Of these 10 patients, 5 died and showed varying degrees of cortical necrosis, the other 5 survived after periods of anuria or oliguria ranging from 2 to 12 days, and all were pregnant women presenting with antepartum hæmorrhage, and with some degree of retroplacental clot. Studies of the renal blood flow were made on 3 surviving patients, and the urine/blood ratio for urea followed in all patients who regained renal function. The estimated renal plasma flow, measured with para aminohippuric acid, was low, and although in 2 cases renal venous catheterisation revealed a low extraction ratio, calculation of the true renal plasma flow showed it to be below normal.

The reduction of plasma flow was more severe and prolonged in a case with oliguria lasting more than 6 days, than in 2 cases with oliguria lasting only 2-3 days. The changes in renal function ran a course identical with those seen in tubular necrosis, eventually recovery was almost complete.

Dr Joeekes thinks there is no fundamental difference in the renal ischaemia apart from the degree of severity which results in either cortical necrosis or acute tubular necrosis. Complete cortical necrosis is the irreversible end point of severe ischaemia, whereas with "incomplete cortical necrosis," in which recovery is possible, the principal lesion is necrosis of the proximal tubules, the ischaemia not being sufficiently severe to cause the death of more than a few isolated glomeruli. In such cases the pattern of events is probably initiated by a low renal blood flow, leading to hypoxia and proximal tubular damage. This gives rise to passive resorption of the glomerular filtrate, interstitial oedema, rise of intrarenal tension, and further reduction of the renal blood flow accompanied by anuria or low specific-gravity oliguria. If the patient survives sufficiently long the tubular epithelium regenerates, diuresis probably coinciding with the relining of the tubules with low poorly differentiated epithelial cells. Further differentiation of the regenerated epithelium allows of nearly complete recovery of renal function.

Prof K J FRANKLIN said that cortical necrosis can be produced experimentally by ischaemia, and he doubts if its production is ever unassociated with ischaemia. The methods used have included continuous or intermittent interruption of the renal circulation, intermittent stimulation of the renal nerves, and administration of various chemical substances, each of the last two produces producing a diversion of cortical blood flow. Chemical substances affecting the denervated as well as the innervated kidney may act through a local nervous reflex mechanism, and Professor Franklin discussed the evidence for the existence of such a mechanism in the kidney, with particular reference to the work of de Mylder. If there is such a mechanism, the aetiological basis of all experimental cortical necroses may be nervously intermediated vasoconstriction, but the possibility of chemical substances acting as direct intrarenal poisons has not yet been excluded.

Professor Franklin went on to describe recent observations on renal changes during parturition in the anaesthetised rabbit, and he suggested provisionally that, in the full term doe, there is a circulating humoral agent (possibly posterior pituitary extract) producing some degree of diversion of the renal cortical blood flow. At the moment of parturition further diversion may be produced by nervous reflexes, possibly from the uterus.

Dr J F HEGGIE observed that the oliguria which occurs during the initial stage of experimental sym-

metrical cortical necrosis is associated with the passage of urine whose composition closely resembles that of glomerular filtrate. He remarked that the tubule cells of the rabbit's kidney regenerate after ischaemia of 1 hour. He does not think that in man ischaemia lasting up to 6 hours would cause permanent damage to the kidney. Dr Heggie has observed in animals the lesions described by Professor Sheehan. In man the renal blood flow is reduced by 50% on assuming the erect posture, and Dr Heggie suggested that pregnancy toxæmia may render unduly irritable the mechanism responsible for this local control.

Mr G. J. SOPHIAN said that inulin clearance tests show that in both toxæmic and normal pregnancy some degree of glomerular shut down may be present, and in toxæmic pregnancy the figures indicate gross afferent spasm. He regards this afferent glomerular arterial constriction as part of an over all mechanism—the "Oxford shunt." This is supremely important in considering the aetiology of cortical necrosis, since there is evidence that the oliguria associated with severe pre-eclampsia is a precursor of the renal breakdown. He envisaged a continuing cortical ischaemic state as responsible for the variable renal disintegration. Certain glomerular afferents are completely functionless, others are still pervious to a diminished blood flow. With the former state complete nephron degeneration

takes place, whilst with the latter—even though the head of pressure is insufficient to allow of glomerular filtration—there is enough oxygenation of the part supplied to maintain survival of the affected nephrons. Mr Sophian's argument was supported by an account of experimental electrical stimulation of the renal nerves which produced considerable oedema of the kidney chiefly of the primary convoluted tubules, and in one case areas of true cortical necrosis. He cited experimental and clinical evidence that a humoral pressor substance is released by the stimulated kidney. In conclusion, he urged the employment of "Pavex caudal analgesia" (R. A. Hingson) so that the underlying and continuingly destructive renal spasm may be directly overcome.

Dr R. H. PARAMORE recalled evidence suggesting that high intra-abdominal pressure is a factor in the aetiology of symmetrical cortical necrosis.

Dr EL ASFOURY expressed the view that large numbers of nerve-cells are present in the chronically denervated rat's kidney.

Prof J. TRUETA emphasised the lability of the renal circulation and the wide range of pathological changes in cortical ischaemia.

Dr G. M. BULL did not favour sympathetic block as a means of treating anuria due to symmetrical cortical necrosis.

Operative Obstetrics

(5th ed.) J. M. MUNRO KERR LL.D., F.R.C.O.G., J. CHASSAR MOIR, F.R.C.S.E. F.R.C.O.G. London: Baillière, Tindall, & Cox 1949. Pp. 948. 63s.

OUR fathers and grandfathers were artists with the materials and methods at their disposal, and made their epoch great by their skill. Now we have more knowledge, a wider and safer choice of tools, and less need for dexterity. The joint authorship of this book spans a gulf in the history of obstetrics, for Professor Munro Kerr, who crossed the bridge between the old and the new in the forefront of a distinguished profession, is here joined by a colleague of a younger generation.

This new edition contains a section on continuous caudal analgesia contributed by Mr J. H. Peel, with a good summary of its uses and contra-indications. The main text gives far more than operative details, much of the pathology of labour, and the experimental work behind it, is described, and as might be expected, the technique of radiological diagnosis in disproportion is fully covered. Historical notes on past and present treatments make excellent reading and enrich the book. Angular pregnancy, a subject often scantily dealt with in British textbooks, is described in the light of cases known to the authors. Pubiotomy and symphysiotomy are defended with some enthusiasm, and many other of the older treatments are described, not because a return to their general use is advocated, but so that the student may recognise a wider range of therapeutic choice.

Practical Haematology

J. V. DACIE, M.B., M.R.C.P. reader in haematology Post-graduate Medical School of London. London: J. & A. Churchill 1950. Pp. 172. 10s. 6d.

THIS useful little book outlines the methods that the author has found of practical value in his department. It is pleasantly didactic and is a welcome change from those books that give lists of methods without indication of relative value. Subjects that belong "to morphology rather than medicine" are omitted, so there is no description of the various cells of blood and bone marrow.

Anyone who follows the methods intelligently will get good results: the text is full of the practical hints that only experience can give. For example, Dr Dacie points out that when oxalate is used as an anticoagulant serious morphological changes occur in the red and white blood-cells within an hour, thus has obvious applications to the practice of sending blood through the post. The accuracy of the various methods used

is discussed at some length and the reader should have precise ideas of the value and significance of variations he observes. Dacie agrees that the red cell count is relatively inaccurate, if not quite so bad as the statisticians would have us believe, in consequence he recommends estimation of the haemoglobin and the haematocrit as a screening test and only does a red cell count if anaemia is shown by the first two tests. The various tests for haemolytic disease are naturally exceptionally well described. We are glad to see the viper venom method for prothrombin estimation decisively condemned. The blood-group section is sensible and not over complicated, but none of the important points about subgroups are passed over. Difficulties like those due to false positive AB groups are fully dealt with. Descriptions of the estimation of the erythrocyte sedimentation rate and of the Paul Bunnell reaction for glandular fever are properly given a place. Finally there are short appendices dealing with formulae, apparatus, and records.

This book can be confidently recommended to registrars and residents in clinical pathology and to technicians studying for the I.M.L.T. haematology certificate. It will give them most of what they need about the quantitative, as distinct from the morphological, parts of haematology.

Heavy Metal Prosthetic Groups and Enzyme Action

OTTO WARBURG. Translator: ALEXANDER LAWSON. London: Oxford University Press 1949. Pp. 230. 18s.

DURING the 1920s Professor Warburg produced two books, *Über die katalytischen Wirkungen der lebendigen Substanz* (1928) and *Über den Stoffwechsel der Tumoren* (1928), consisting almost entirely of collections of his previously published papers. The present volume lies in character somewhere between these earlier works and a monograph. In it he describes the results of the work of his laboratory on heavy metal-containing enzymes, the researches and opinions of other workers being, on the whole, considered only in so far as they lead up to, agree with, disagree with, or confirm his own.

Most of the book is concerned with the *Atmungsferment* (respiratory enzyme) here called the "oxygen transporting enzyme." The earlier work with models and on the inhibition of cell respiration by cyanide, carbon monoxide, and hydrogen sulphide leads up to the triumphant determination (1928-29) of the photochemical absorption spectrum of the respiratory enzyme. The painstaking control experiments are described, and it is seen that these were still continuing during the late war in the study by Buther and Negelein (1942) of the dissociation by light of carboxyhaemoglobin and carboxymyoglobin.

Symmetrical Cortical Necrosis of the Kidney

At a meeting of the section of obstetrics on Nov 17, with Mr V B GREEN ARMYTAGE, president of the section, in the chair, a discussion on symmetrical cortical necrosis of the kidney was opened by Prof H L SHEEHAN.

He described the pathological findings in the kidney at various times after concealed accidental hæmorrhage. He attributed cortical necrosis and other less severe renal lesions to angospasm occurring approximately coincidentally with the intra uterine hæmorrhage. Evidence of parenchymal damage or death, and necrosis and thrombosis of arteries, appears when the spasm relaxes and blood flows into the damaged area. The severity of the histological changes are correlated with the extent and duration of the antecedent angospasm, and these changes may be classified into nine types.

Type-1 lesions result from spasm of the afferent glomerular arteriole lasting 15-30 minutes, there is subsequent albuminuria and occasionally some cast formation in collecting tubules. The kidney usually returns to normal in 1-2 days.

Type-2 lesions follow afferent arteriolar spasm lasting about 1 hour. Hyaline droplet formation or colloid degeneration of the proximal convoluted tubules progresses between 6 and 24 hours after the uterine hæmorrhage, but these changes disappear in the next 2 or 3 days. Colloid casts may develop in the tubules of the intermediate zone and lead to more serious impairment of renal function.

Type-3 lesions follow afferent arteriolar spasm lasting 2-3 hours. The proximal tubule cells are killed, but are histologically unaltered until the blood flow returns, when they become necrotic. The lesions are maximal after 24 hours. Signs of regeneration appear after 3 days, and the tubules are relined with flattened epithelium after 6 days, this may atrophy later. Extensive tubular necrosis produces great oliguria for a week or more and may lead to death.

Type-4 lesions—"benign thrombosis of glomeruli"—follow 4-5 hours' arteriolar spasm with subsequent relaxation. Thrombi lie freely in the centre of the glomerular capillaries. The cortex otherwise shows a type-3 lesion.

Type-5—"focal cortical necrosis"—is characterised by stasis or thrombosis of occasional glomerular tufts and afferent arterioles which have been killed by focal spasm in these arterioles lasting 8-10 hours. These lesions develop at about 12-14 hours. A few small foci of cortical necrosis result. As with all other types of cortical necrosis, the remaining parenchyma is extensively involved by the type-3 lesion.

In *type-6*—"minor cortical necrosis"—the spasm begins in afferent arterioles but later involves the distal segments of intralobular arteries where it lasts 8-10 hours. The distal part of the arterial tree, and the glomeruli and tubules supplied by the affected artery, die. Arterial necrotic lesions and thrombosis occur when the spasm relaxes.

In *type-7*—"patchy cortical necrosis"—the spasm begins in afferent arterioles but subsequently moves back to many of the intralobular arteries at about mid-cortex. It lasts about 15-18 hours. When the spasm relaxes there is a characteristic arterial thrombosis. The prognosis is very poor as so much of the cortex is destroyed.

Type-8 lesions—"gross cortical necrosis"—result from an initial afferent arteriole spasm which later passes back to involve the intralobular artery distal to the origin of the afferent arterioles of the basal glomeruli. The spasm lasts about 24 hours and produces death of most of the cortex. When it relaxes, thrombosis occurs in the dead arteries. This condition is always fatal, usually within 7-10 days.

Type-9 lesions—a less common variant of "gross cortical necrosis"—are due to the arterial spasm lasting 2-3 days. An occlusive thrombus forms at the proximal

extremity of the affected arterial segment, and there are no lesions referable to the passage of blood into the damaged area.

Dr A M JOEKES, together with Dr G M BULL and Dr K C LOWE, has studied 120 cases of anuria or low specific gravity oliguria, in 10 of which there was a possible diagnosis of cortical necrosis. Of these 10 patients, 5 died and showed varying degrees of cortical necrosis, the other 5 survived after periods of anuria or oliguria ranging from 2 to 12 days, and all were pregnant women presenting with antepartum hæmorrhage, and with some degree of retroplacental clot. Studies of the renal blood flow were made on 3 surviving patients, and the urine/blood ratio for urea followed in all patients who regained renal function. The estimated renal plasma flow, measured with para aminohippuric acid, was low, and although in 2 cases renal venous catheterisation revealed a low extraction ratio, calculation of the true renal plasma flow showed it to be below normal.

The reduction of plasma flow was more severe and prolonged in a case with oliguria lasting more than 6 days, than in 2 cases with oliguria lasting only 2-3 days. The changes in renal function ran a course identical with those seen in tubular necrosis, eventually recovery was almost complete.

Dr Joeekes thinks there is no fundamental difference in the renal ischaemia apart from the degree of severity which results in either cortical necrosis or acute tubular necrosis. Complete cortical necrosis is the irreversible end point of severe ischaemia, whereas with "incomplete cortical necrosis," in which recovery is possible, the principal lesion is necrosis of the proximal tubules, the ischaemia not being sufficiently severe to cause the death of more than a few isolated glomeruli. In such cases the pattern of events is probably initiated by a low renal blood flow, leading to hypoxia and proximal tubular damage. This gives rise to passive resorption of the glomerular filtrate, interstitial oedema, rise of intrarenal tension, and further reduction of the renal blood flow accompanied by anuria or low specific-gravity oliguria. If the patient survives sufficiently long the tubular epithelium regenerates, diuresis probably coinciding with the relining of the tubules with low poorly differentiated epithelial cells. Further differentiation of the regenerated epithelium allows of nearly complete recovery of renal function.

Prof K J FRANKLIN said that cortical necrosis can be produced experimentally by ischaemia, and he doubts if its production is ever unassociated with ischaemia. The methods used have included continuous or intermittent interruption of the renal circulation, intermittent stimulation of the renal nerves, and administration of various chemical substances, each of the last two procedures producing a diversion of cortical blood flow. Chemical substances affecting the denervated as well as the innervated kidney may act through a local nervous reflex mechanism, and Professor Franklin discussed the evidence for the existence of such a mechanism in the kidney, with particular reference to the work of de Muylder. If there is such a mechanism, the aetiological basis of all experimental cortical necroses may be nervously intermediated vasoconstriction, but the possibility of chemical substances acting as direct intrarenal poisons has not yet been excluded.

Professor Franklin went on to describe recent observations on renal changes during parturition in the anaesthetised rabbit, and he suggested provisionally that, in the full term doe, there is a circulating humoral agent (possibly posterior pituitary extract) producing some degree of diversion of the renal cortical blood flow. At the moment of parturition further diversion may be produced by nervous reflexes possibly from the uterus. Dr J F HEGGIE observed that the oliguria which occurs during the initial stage of experimental sym-

metrical cortical necrosis is associated with the passage of urine whose composition closely resembles that of glomerular filtrate. He remarked that the tubule cells of the rabbit's kidney regenerate after ischaemia of 1 hour. He does not think that in man ischaemia lasting up to 6 hours would cause permanent damage to the kidney. Dr Heggie has observed in animals the lesions described by Professor Sheehan. In man the renal blood flow is reduced by 50% on assuming the erect posture, and Dr Heggie suggested that pregnancy toxæmia may render unduly irritable the mechanism responsible for this local control.

Mr G. J. SOPHIAN said that mulin clearance tests show that in both toxæmic and normal pregnancy some degree of glomerular shut down may be present, and in toxæmic pregnancy the figures indicate gross afferent spasm. He regards this afferent glomerular arterial constriction as part of an over all mechanism—the "Oxford shunt". This is supremely important in considering the ætiology of cortical necrosis, since there is evidence that the oliguria associated with severe pre-eclampsia is a precursor of the renal breakdown. He envisaged a continuing cortical ischaemic state as responsible for the variable renal disintegration. Certain glomerular afferents are completely functionless, others are still pervious to a diminished blood flow. With the former state, complete nephron degeneration

takes place, whilst with the latter—even though the head of pressure is insufficient to allow of glomerular filtration—there is enough oxygenation of the part supplied to maintain survival of the affected nephrons. Mr Sophian's argument was supported by an account of experimental electrical stimulation of the renal nerves which produced considerable oedema of the kidney chiefly of the primary convoluted tubules, and in one case areas of true cortical necrosis. He cited experimental and clinical evidence that a humoral pressor substance is released by the stimulated kidney. In conclusion, he urged the employment of "Pavex caudal analgesia" (R. A. Hingson) so that the underlying and continuingly destructive renal spasm may be directly overcome.

Dr R. H. PARAMORE recalled evidence suggesting that high intra-abdominal pressure is a factor in the ætiology of symmetrical cortical necrosis.

Dr EL ASFOURY expressed the view that large numbers of nerve-cells are present in the chronically denervated rat's kidney.

Prof J. TRUETA emphasised the lability of the renal circulation and the wide range of pathological changes in cortical ischaemia.

Dr G. M. BULL did not favour sympathetic block as a means of treating anuria due to symmetrical cortical necrosis.

Reviews of Books

Operative Obstetrics

(5th ed.) J. M. MUNRO KERR, LL.D., F.R.C.O.G. J. CHASSAR MOIR, F.R.C.S.E. F.R.C.O.G. London: Baillière, Tindall, & Cox. 1949. Pp. 943. 63s.

OUR fathers and grandfathers were artists with the materials and methods at their disposal, and made their epoch great by their skill. Now we have more knowledge, a wider and safer choice of tools, and less need for dexterity. Symmetrical Cortical Necrosis of the Kidney

At a meeting of the section of obstetrics on Nov 17, with Mr V B GREEN ARMYTAGE, president of the section, in the chair, a discussion on symmetrical cortical necrosis of the kidney was opened by Prof H L SHEEHAN.

He described the pathological findings in the kidney at various times after concealed accidental hæmorrhage. He attributed cortical necrosis and other less severe renal lesions to angiospasm occurring approximately coincidentally with the intra uterine hæmorrhage. Evidence of parenchymal damage or death, and necrosis and thrombosis of arteries, appears when the spasm relaxes and blood flows into the damaged area. The severity of the histological changes are correlated with the extent and duration of the antecedent angiospasm, and these changes may be classified into nine types.

Type-1 lesions result from spasm of the afferent glomerular arteriole lasting 15-30 minutes; there is subsequent albuminuria and occasionally some cast formation in collecting tubules. The kidney usually returns to normal in 1-2 days.

Type 2 lesions follow afferent arteriolar spasm lasting about 1 hour. Hyaline droplet formation or colloid degeneration of the proximal convoluted tubules progresses between 6 and 24 hours after the uterine hæmorrhage, but these changes disappear in the next 2 or 3 days. Colloid casts may develop in the tubules of the intermediate zone and lead to more serious impairment of renal function.

Type-3 lesions follow afferent arteriolar spasm lasting 2-3 hours. The proximal tubule cells are killed, but are histologically unaltered until the blood flow returns, when they become necrotic. The lesions are maximal after 24 hours. Signs of regeneration appear after 3 days, and the tubules are relined with flattened epithelium after 6 days; this may atrophy later. Extensive tubular necrosis produces great oliguria for a week or more and may lead to death.

Type-4 lesions—"benign thrombosis of glomeruli"—follow 4-5 hours' arteriolar spasm with subsequent relaxation. Thrombi lie freely in the centre of the glomerular capillaries. The cortex otherwise shows a type-3 lesion.

Type 5—"focal cortical necrosis"—is characterised by stasis or thrombosis of occasional glomerular tufts and afferent arterioles which have been killed by focal spasm in these arterioles lasting 8-10 hours. These lesions develop at about 12-14 hours. A few small foci of cortical necrosis result. As with all other types of cortical necrosis, the remaining parenchyma is extensively involved by the type-3 lesion.

In *type 6*—"minor cortical necrosis"—the spasm begins in afferent arterioles but later involves the distal segments of intralobular arteries where it lasts 8-10 hours. The distal part of the arterial tree, and the glomeruli and tubules supplied by the affected artery, die. Arterial necrotic lesions and thrombosis occur when the spasm relaxes.

In *type 7*—"patchy cortical necrosis"—the spasm begins in afferent arterioles but subsequently moves back to many of the intralobular arteries at about mid-cortex. It lasts about 15-18 hours. When the spasm relaxes there is a characteristic arterial thrombosis. The prognosis is very poor as so much of the cortex is destroyed.

Type-8 lesions—"gross cortical necrosis"—result from an initial afferent arteriole spasm which later passes back to involve the intralobular artery distal to the origin of the afferent arterioles of the basal glomeruli. The spasm lasts about 24 hours and produces death of most of the cortex. When it relaxes thrombosis occurs in the dead arteries. This condition is always fatal, usually within 7-10 days.

Type-9 lesions—a less common variant of "gross cortical necrosis"—are due to the arterial spasm lasting 2-3 days. An occlusive thrombus forms at the proximal

extremity of the affected arterial segment, and there are no lesions referable to the passage of blood into the damaged area.

Dr A M JOEKES, together with Dr G M BULL and Dr K C LOWE, has studied 120 cases of anuria or low specific gravity oliguria, in 10 of which there was a possible diagnosis of cortical necrosis. Of these 10 patients, 5 died and showed varying degrees of cortical necrosis, the other 5 survived after periods of anuria or oliguria ranging from 2 to 12 days, and all were pregnant women presenting with antepartum hæmorrhage, and with some degree of retroplacental clot. Studies of the renal blood flow were made on 3 surviving patients, and the urine/blood ratio for urea followed in all patients who regained renal function. The estimated renal plasma flow, measured with para aminoluppuric acid, was low, and although in 2 cases renal venous catheterisation revealed a low extraction ratio, calculation of the true renal plasma flow showed it to be below normal.

The reduction of plasma flow was more severe and prolonged in a case with oliguria lasting more than 8 days, than in 2 cases with oliguria lasting only 2-3 days. The changes in renal function ran a course identical with those seen in tubular necrosis, eventually recovery was almost complete.

Dr Joekes thinks there is no fundamental difference in the renal ischæmia apart from the degree of severity which results in either cortical necrosis or acute tubular necrosis. Complete cortical necrosis is the irreversible end point of severe ischæmia, whereas with "incomplete cortical necrosis," in which recovery is possible, the principal lesion is necrosis of the proximal tubules, the ischæmia not being sufficiently severe to cause the death of more than a few isolated glomeruli. In such cases the pattern of events is probably initiated by a low renal blood flow, leading to hypoxia and proximal tubular damage. This gives rise to passive resorption of the glomerular filtrate, interstitial œdema, rise of intrarenal tension, and further reduction of the renal blood flow accompanied by anuria or low specific-gravity oliguria. If the patient survives sufficiently long the tubular epithelium regenerates, diuresis probably coinciding with the relining of the tubules with low poorly differentiated epithelial cells. Further differentiation of the regenerated epithelium allows of nearly complete recovery of renal function.

Prof K J FRANKLIN said that cortical necrosis can be produced experimentally by ischæmia, and he doubts if its production is ever unassociated with ischæmia. The methods used have included continuous or intermittent interruption of the renal circulation, intermittent stimulation of the renal nerves, and administration of various chemical substances, each of the last two procedures producing a diversion of cortical blood flow. Chemical substances affecting the denervated as well as the innervated kidney may act through a local nervous reflex mechanism, and Professor Franklin discussed the evidence for the existence of such a mechanism in the kidney, with particular reference to the work of de Muylder. If there is such a mechanism, the ætiological basis of all experimental cortical necroses may be nervously intermediated vasoconstriction, but the possibility of chemical substances acting as direct intrarenal poisons has not yet been excluded.

Professor Franklin went on to describe recent observations on renal changes during parturition in the anaesthetised rabbit, and he suggested provisionally that, in the full term doe, there is a circulating humoral agent (possibly posterior pituitary extract) producing some degree of diversion of the renal cortical blood flow. At the moment of parturition further diversion may be produced by nervous reflexes, possibly from the uterus.

Dr J F HEGGIE observed that the oliguria which occurs during the initial stage of experimental sym-

metrical cortical necrosis is associated with the passage of urine whose composition closely resembles that of glomerular filtrate. He remarked that the tubule cells of the rabbit's kidney regenerate after ischaemia of 1 hour. He does not think that in man ischaemia lasting up to 6 hours would cause permanent damage to the kidney. Dr Heggie has observed in animals the lesions described by Professor Sheehan. In man the renal blood flow is reduced by 50% on assuming the erect posture, and Dr Heggie suggested that pregnancy toxæmia may render unduly irritable the mechanism responsible for this local control.

Mr G. J. SOPHIAN said that inulin clearance tests show that in both toxæmic and normal pregnancy some degree of glomerular shut down may be present, and in toxæmic pregnancy the figures indicate gross afferent spasm. He regards this afferent glomerular arterial constriction as part of an over all mechanism—the "Oxford shunt". This is supremely important in considering the ætiology of cortical necrosis, since there is evidence that the oliguria associated with severe pre-eclampsia is a precursor of the renal break down. He envisaged a continuing cortical ischaemic state as responsible for the variable renal disintegration. Certain glomerular afferents are completely functionless, others are still pervious to a diminished blood flow. With the former state, complete nephron degeneration

takes place, whilst with the latter—even though the head of pressure is insufficient to allow of glomerular filtration—there is enough oxygenation of the part supplied to maintain survival of the affected nephrons. Mr Sophian's argument was supported by an account of experimental electrical stimulation of the renal nerves which produced considerable œdema of the kidney chiefly of the primary convoluted tubules, and in one case areas of true cortical necrosis. He cited experimental and clinical evidence that a humoral pressor substance is released by the stimulated kidney. In conclusion, he urged the employment of "Pavex caudal analgesia" (R. A. Hingson) so that the underlying and continuingly destructive renal spasm may be directly overcome.

Dr R. H. PARAMORE recalled evidence suggesting that high intra-abdominal pressure is a factor in the ætiology of symmetrical cortical necrosis.

Dr EL ASFOURY expressed the view that large numbers of nerve-cells are present in the chronically denervated rat's kidney.

Prof J. TRUETA emphasised the lability of the renal circulation and the wide range of pathological changes in cortical ischaemia.

Dr G. M. BULL did not favour sympathetic block as a means of treating anuria due to symmetrical cortical necrosis.

Reviews of Books

Operative Obstetrics

(5th ed.) J. M. MUNRO KERR, LL.D., F.R.C.O.G., J. CHASSAR MOIR, F.R.C.S.E., F.R.C.O.G. London: Baillière, Tindall, & Cox, 1949. Pp. 948. 83s.

OUR fathers and grandfathers were artists with the materials and methods at their disposal, and made their epoch great by their skill. Now we have more knowledge, a wider and safer choice of tools, and less need for dexterity. The joint authorship of this book spans a gulf in the history of obstetrics, for Professor Munro Kerr, who crossed the bridge between the old and the new in the forefront of a distinguished procession, is here joined by a colleague of a younger generation.

This new edition contains a section on continuous caudal analgesia contributed by Mr J. H. Peel, with a good summary of its uses and contra-indications. The main text gives far more than operative details, much of the pathology of labour, and the experimental work behind it, is described, and as might be expected, the technique of radiological diagnosis in disproportion is fully covered. Historical notes on past and present treatments make excellent reading and enrich the book. Angular pregnancy, a subject often scantily dealt with in British textbooks, is described in the light of cases known to the authors. Pubiotomy and symphysiotomy are defended with some enthusiasm, and many other of the older treatments are described, not because a return to their general use is advocated, but so that the student may recognise a wider range of therapeutic choice.

Practical Hæmatology

J. V. DACIE, M.B., M.R.C.P., reader in hæmatology, Post-graduate Medical School of London. London: J. & A. Churchill, 1950. Pp. 172. 10s. 6d.

THIS useful little book outlines the methods that the author has found of practical value in his department. It is pleasantly didactic and is a welcome change from those books that give lists of methods without indication of relative value. Subjects that belong "to morphology rather than medicine" are omitted, so there is no description of the various cells of blood and bone-marrow.

Anyone who follows the methods intelligently will get good results: the text is full of the practical hints that only experience can give. For example, Dr Dacie points out that when oxalate is used as an anticoagulant serious morphological changes occur in the red and white blood-cells within an hour, thus has obvious applications to the practice of sending blood through the post. The accuracy of the various methods used

is discussed at some length and the reader should have precise ideas of the value and significance of variations he observes. Dacie agrees that the red cell count is relatively inaccurate, if not quite so bad as the statisticians would have us believe, in consequence he recommends estimation of the hæmoglobin and the hæmatocrit as a screening test and only does a red cell count if anæmia is shown by the first two tests. The various tests for hæmolytic disease are naturally exceptionally well described. We are glad to see the viper venom method for prothrombin estimation decisively condemned. The blood-group section is sensible and not over-complicated, but none of the important points about subgroups are passed over. Difficulties like those due to false positive AB groups are fully dealt with. Descriptions of the estimation of the erythrocyte sedimentation rate and of the Paul-Bunnell reaction for glandular fever are properly given a place. Finally there are short appendices dealing with formulae, apparatus, and records.

This book can be confidently recommended to registrars and residents in clinical pathology and to technicians studying for the I.M.L.T. hæmatology certificate. It will give them most of what they need about the quantitative, as distinct from the morphological, parts of hæmatology.

Heavy Metal Prosthetic Groups and Enzyme Action

OTTO WARBURG, Translator: ALEXANDER LAWSON. London: Oxford University Press, 1949. Pp. 230. 18s.

DURING the 1920s Professor Warburg produced two books, *Über die katalytischen Wirkungen der lebendigen Substanz* (1928) and *Über den Stoffwechsel der Tumoren* (1928), consisting almost entirely of collections of his previously published papers. The present volume lies in character somewhere between these earlier works and a monograph. In it he describes the results of the work of his laboratory on heavy metal containing enzymes, the researches and opinions of other workers being, on the whole, considered only in so far as they lead up to, agree with, disagree with, or confirm his own.

Most of the book is concerned with the *Atmungsferment* (respiratory enzyme) here called the oxygen transporting enzyme. The earlier work with models and on the inhibition of cell respiration by cyanide, carbon monoxide, and hydrogen sulphide leads up to the triumphant determination (1928-29) of the photochemical absorption spectrum of the respiratory enzyme. The painstaking control experiments are described, and it is seen that these were still continuing during the late war, in the study by Bücher and Negelein (1942) of the dissociation by light of carboxy-hæmoglobin and carboxymyoglobin.

The rest of the book is concerned with fairly recent work by Professor Warburg and his colleagues on various metal containing enzyme systems, phenol oxidase, the hydrogen liberating enzyme in butyric acid fermentation and aldolase, the reduction of quinine by chloroplasts and disintegrated chloroplasts, and finally on the quantum requirement of CO₂ assimilation. The translator has done his task well and the author's simple, clear, and trenchant style has not been lost.

"The discussions which took place with Willstätter, Wieland, and Euler about oxygen transporting iron began in 1922 and ended in 1925. They were brought to an end by a controversy with Kellin which started in 1929 and finished in 1939." In this opening paragraph of chapter 16 Professor Warburg epitomises much of his career and of this book. He has seen fit to return to the controversies of 10-30 years ago, and his attacks have softened little with time. Professor Kellin, in a review¹ of the German version of this book, regretted that Professor Warburg had not rather elected to give a well-balanced historical account, and criticised various of his interpretations of the history of the subject. Into this latest, albeit mild, clash of the two great antagonists we do not venture to intrude. But this book raises again the question whether controversy in general is a necessary or even desirable element in scientific research. In so far as it lubricates research by psychical stimulation of the workers it is of some value. In so far as it estranges workers it is harmful, some of the great advances of today are coming from mutual help between different groups. Much of it has been unnecessary, arising from the use of language rather than from observation of fact. The echoes of the resounding polemics of the last century are dying away, and in private and scientific life individuals are becoming milder and more conciliatory. Man tends to hurt feelings less and less as his power of destruction becomes greater and greater. It may be that the revived polemics of this book are sounds of an era that is passing away.

The National Health Service

ROGER ORMBOD, M.A., B.M., barrister at law, HARRIS WALKER, barrister at law. London. Butterworth 1950. Pp 470. 27s 6d.

THIS book contains the texts of the National Health Service Acts, 1946 and 1949, annotated by Mr John H. Ellison, barrister-at-law, together with a clearly written introduction of 100 pages in which the meaning of the Acts and the statutory instruments to which they have given rise is set out in non-technical language with full references. The final section of the book is reprinted from the Butterworth Emergency Legislation Service and contains all the statutory rules and orders and statutory instruments made under the National Health Service Acts from 1946 to April, 1950. The result is an authoritative reference book which will be of real value to lawyers and to all administrators, whether medical or lay, connected with the National Health Service.

A Naturalist in the Gran Chaco

SIR JOHN GRAHAM KERR, F.R.S., honorary fellow of Christ's College, Cambridge, and sometime regius professor of zoology in the University of Glasgow. London. Cambridge University Press. 1950. Pp 236. 21s.

BASED ON Sir John Graham Kerr's diaries of sixty and fifty-four years ago this account of thrilling adventures and scientific discovery is in the tradition of Darwin's voyage in H.M.S. *Beagle* and of Bates's *Naturalist on the Amazons*, and are therefore a useful corrective to some modern books on the same region.

Two expeditions are described. The first, in 1889-91, was an exploratory survey of the Pilcomayo river from the Paraná to the frontiers of Bolivia. Unfortunately most of the valuable zoological collections were mysteriously lost, but the young student, Graham Kerr, became an intimate friend of the extremely primitive Natokoi Indians with whom he hunted as a lone white, and whose language he tried to note down phonetically. One long chapter is devoted to a description of this tribe. Commenting on the wonderful faith of the Natokoi, Sir John says "Not only is the individual promptly eliminated, but even the towards disability is being constantly weeded out

so that, as in the case of wild animals, the race is maintained at the highest pitch of health"—a type of health service which civilisation happily denies to the rest of us. The second expedition, in 1896-97, was to dig out *Lepidosiren* from its native mud and was entirely successful. To ornithologists the book is specially attractive, conjuring up magnificent pictures of South American bird life.

Roentgen Diagnosis of Diseases of the Skull

MAX RITVO, M.D., assistant professor of radiology Harvard Medical School London. Cassell 1949. Pp 409. £5 13s 6d.

THE standards of radiography and interpretation of films are often very different in neurological centres from the standards in general hospitals, where few but traumatic cases may be investigated. A new textbook on the radiology of the skull may thus become a reference work for those who find skull pictures unfamiliar. Dr Ritvo's book, one of an *Annals of Roentgenology* series in which a high standard has already been set, deals well with the questions of technique and normal anatomy. The text throughout is excellent, though more detail might perhaps have been allowed to the sections on vascular markings, pressure changes, and the temporal bone. It is good to see evidence of the author's close collaboration with his clinical colleagues. In this branch of radiology, as he points out in his preface, such co-operation is vital. Unfortunately the reproduction of many of the numerous illustrations is not so good as might have been expected. Nor do the editors of the series seem to realise that it is impossible to dissociate changes originating in the bony structures of the skull from those which arise from cerebral pathological change. The author evidently feels this, for a brief but well written section on cerebral angiography has crept in. But there is no mention of other methods of examination of the cranial contents except statements—which some may consider sweeping—on the relative importance of air studies and angiography. It is a pity that a book so well compiled should have been hampered by the limitations of its title.

The Eye and its Diseases (2nd ed. Philadelphia & London. W. B. Saunders 1949. Pp 1092. 80s.)—This important book, edited by Dr Conrad Berens, was first published 14 years ago and was at once recognised as a reference work of the highest class. Its 92 authors, drawn from hospitals and universities in North and South America, Europe and Australia, give an international picture of ophthalmic medicine, and, to a lesser degree, of ophthalmic surgery. Some of the illustrations are too small to be clear, while others are too faint. The surgery of the eye has been condensed into 120 pages, which allows of only a few illustrations and perhaps this is the least useful part of the book but taken as a whole it is an outstanding work.

Savill's System of Clinical Medicine (13th ed. London. Edward Arnold 1950. Pp 1198. 35s.)—Dr E. C. Warner, the editor, has made no great alterations in this new edition of 'Savill,' but has arranged for much revision and the addition of some new chapters. The twenty odd contributors have used the Savill approach, working from symptom to diagnosis via physical signs and not from a disease description to symptoms and signs. The method has obvious advantages as well as certain drawbacks, and has long proved popular. The new edition has in its 1100 pages a great mass of information, no wasted space, and not many illustrations. Nevertheless it remains readable, and with comparatively few expensive plates and photographs it is offered at a relatively low price for so full a textbook.

Acute Laryngotracheobronchitis (New York. Grune & Stratton 1949. Pp 197. \$5.)—Dr A. Harry Neffson believes that there is still much confusion about the group of conditions commonly called 'croup.' The incidence, pathology, bacteriology, symptomatology, diagnosis, and differential diagnosis of this symptom complex are clearly discussed. Special emphasis is laid on the characteristic features of supraglottic laryngeal oedema—a condition requiring a particular form of treatment promptly given. Half the book is devoted to treatment, medical and surgical. The complications of tension pneumothorax and mediastinal emphysema after tracheotomy are fully discussed. The book contains much of interest to general practitioners, paediatricians, and otolaryngologists.

THE LANCET

LONDON SATURDAY, DEC 2, 1950

Field Work for Students

THE part of medicine that the student sees in a teaching hospital is obviously very important, but is not of course a fair sample of the whole. The patients belong to selected groups and are isolated from their environment. Our method has something in common with that of the naturalist who introduces the study of butterflies and moths by demonstrating his collection of insects displayed in cabinets—a collection doubtless containing some rare species but probably omitting nearly all the microlepidoptera so numerous in field and wood. "Never mind," the teacher may say "one must proceed methodically, doing one thing at a time. What we teach here is principles and skills, and the man with a solid foundation of hospital medicine can easily adapt himself to whatever medical circumstances he finds." Perhaps in former days this was true enough, but latterly the argument has carried less and less conviction. Not only is it evident that the newly qualified are nowadays insufficiently equipped for immediate general practice, but also it is all too clear that many of them have lost the taste for it they once possessed. COLLINGS¹ rightly concluded that "medical education at present tends to direct the student away from general practice." The student, as MACLEOD² puts it, becomes wrongly oriented towards such work, he tends to despise minor disorders, and probably feels guilty when he comes to practise without being able to apply the scientific methods he has been taught.

BROTHERSTON³ lays on hospital teachers some of the blame for lessening the prestige once attached to the family doctor's work, for during the students' impressionable years they are apt to make him regard the social medicine of general practice as an inferior substitute for the "real" medicine of the hospitals. More and more teachers recognise this risk, and the remedy lies largely with them. Few hospital teachers, however, have actually been in general practice, and even fewer feel that it matters more than their own specialty. Would it not be wise then to ensure that the student throughout his clinical years is kept aware of the family doctor's work, either by taking part in it occasionally or at least by talks or lectures? The Cohen Committee⁴ did not approve of practitioners teaching in the hospital wards, or taking students on their domiciliary rounds and certainly it would be foolish, merely on the ground that "something must be done," to try to strengthen the hospital educational system by compulsory transfusion of blood from incompatible groups outside. But in actual fact a little preliminary cross matching will prevent the more dangerous reactions, and in a number of schools a few lectures by a visiting practi-

tioner have formed an innocuous and indeed popular part of the course. At St Mary's Hospital not only are informal lectures given by a general practitioner but visits are arranged to allow students to see the set up of a general practice, and to meet and talk to the practitioner's allies—secretaries, dispensers, district nurses, MOHS, and district visitors. An opportunity is given for the student to stay for a week with a general practitioner, to sit by his side in his consulting room, and to accompany him on his visits. It is only a brief glance he gets of general practice, but he can take it at a time when he is still making up his mind which branch of medicine he would like to follow, and above all it gives him an idea, while he is still learning, of the uses to which he will probably have to apply his knowledge. His interest is thus directed to those departments of the hospital less likely to provide him with examination subjects but more intimately linked with his future work.

Describing a more ambitious scheme by which, at Boston, Mass., senior students spend a month working on the district and visiting people's homes, the Commonwealth Fund⁵ says that the effect on the student is electric. As the dean, Dr JAMES M FAULKNER, remarks,

"it shows him that his previous training in the various medical and surgical specialties is partial and incomplete. Even if all the information acquired in the individual courses is synthesised, it is still inadequate if it does not take into account the environment and the patient's reaction to it. It seems highly desirable for the student to come to this realisation as an undergraduate rather than to rely on his finding it out for himself from experience in practice."

In Boston the district work is done among the sick poor under the auspices of a hospital, but even more might be learnt by working as an apprentice in an ordinary practice—a plan which, as Dr BABER⁶ argues, would be good for the practitioner as well as the student. A great deal of first class medicine is being practised all over this country, by able men, under good conditions built up by their own individual effort. This tradition of fine service should be handed on to the younger generation early in their career, and a high standard of general practice should in this way be included automatically in their medical thought. Too many of our present family doctors remain apparently satisfied with poor conditions simply because they were not given a standard at which to aim during their early struggles. It is encouraging therefore to hear that one of the London schools is considering whether a month's work with a practitioner could form part of the normal undergraduate course.

Naturally, during the years when health centres have been regarded as the best means of restoring urban general practice, plans have been made for using them for teaching students. A health centre close beside each undergraduate teaching school could serve as the field department of those who teach, explicitly or implicitly, the social side of medicine, and the practitioners on its staff might have a longed for opportunity of showing how practice can be conducted when conditions are favourable. Since the days when we optimistically spoke of a "district with a population of perhaps 100,000 and

containing half a dozen health centres" where students could see general practice at its best,⁷ the sights of planners have been somewhat lowered. Nevertheless, a great deal of effort and thought has been put into projected centres in Manchester, Birmingham, and elsewhere, where it is hoped that practitioners will join with each other and with the universities in giving the coming generation a new and better idea of general practice. For the moment, however, these remain only projects, and meanwhile it is most valuable to have an account of "a teaching general practice" which already has a long history and is now in a phase of rapid development. On p. 695 Dr RICHARD SCOTT describes what is being attempted and done at Edinburgh, and, though the scale is small, readers must be impressed by the advantage to the student of seeing medicine practised as a whole, with the patients in more or less natural surroundings.

Clouds over Rutin and "Vitamin" P

TROUBLE is no novelty to vitamin P—the very name hesperidin suggests disaster as well as hope, western isles, and lemons—but it will not easily live down the authoritative American decision to erase its name from the list of vitamins. Rutin, a closely related substance whose properties may seem to the uninitiated hopelessly confused with those of ex-vitamin P, has never aspired to a place on the vitamin list beside its kinsman but is now in danger of being burnt on the same pyre.

Vitamin P was introduced by SZENT GYORGYI⁸ in 1936. Its active material, a flavone which he named citrin, was later shown to be a mixture of the glucosides of hesperidin and of eriodictyol. Citrin was said to rectify increased capillary permeability in patients with non thrombocytopenic purpura and to prolong the survival of scorbutic guinea-pigs, but attempts to repeat these observations had conflicting results, even in the hands of SZENT GYORGYI himself.⁹ In the next few years SCARBOROUGH and STEWART¹⁰ described the clinical picture of vitamin-P deficiency in man, and the minimum daily requirement of hesperidin was set as high as 3 g.¹¹ Vitamins P and C are both constituents of citrus fruit and green vegetables, but the bleeding arising from deficiency of the two vitamins was said to be distinct. Only rather scanty evidence of hesperidin's clinical value has been added in the subsequent ten years. Deficiency of vitamin P is not easy to establish, because, as BICKNELL and PRESCOTT¹² point out, undue permeability of the capillaries occurs in various other conditions and is not known to be the primary cause of any form of purpura. There are many possible fallacies—for example,¹³ even a small effusion of blood into the subcutaneous tissues or the alimentary tract may increase capillary resistance for some days. Then the methods of measuring capillary fragility have been criticised, and it is not clear how closely these measurements are related to clinical hæmorrhages. In their report to the Council of

Pharmacy and Chemistry of the American Medical Association, CLARK and MACKAY¹⁴ question whether vitamin P has any vitamin-like activity. The Federation of American Societies of Experimental Biology goes further¹⁵, on the grounds that neither its identity nor its activity have been fully substantiated, they recommend that the term vitamin P should be dropped altogether.

The first mention of rutin in these columns was in 1946,¹⁶ when this substance, a flavone obtained from buckwheat, was said to be useful in hæmorrhagic conditions associated with hypertension. In cases of increased capillary fragility, as shown by Gothlin's technique, it was claimed that rutin would restore normal capillary resistance. Its supposed action thus resembles that of vitamin P, though there has been no suggestion that rutin is an essential constituent of our food. Since 1946, though it has been made and prescribed in this country, no convincing therapeutic successes with rutin have been published, but there have been some failures. Thus LEVITT and colleagues¹⁷ gave it to 12 diabetics with increased capillary fragility and retinal hæmorrhages and noted no apparent effect. GLASS¹⁸ has reported 5 cases of hereditary hæmorrhagic telangiectasia which were unchanged by two or three years' treatment with rutin, but their capillary resistances were normal throughout. Another patient, with a lifelong history of bruising and abnormal capillary fragility, seemed to benefit from a six months' course of rutin.

A reliable specific remedy is badly needed for hæmorrhage occurring in conditions with increased capillary fragility—the Henoch-Schönlein and toxic purpuras, hypertension, and radiation sickness. It was therefore well worth while to reinvestigate the pharmacological actions of rutin and similar flavonoid compounds occurring in plants. In their report to the A.M.A., CLARK and MACKAY¹⁴ describe investigations into the absorption and excretion of these substances. Animal experiments by several workers had shown that when the substances are given parenterally they are excreted in the urine unchanged. If therefore they are given to man and are appreciably absorbed, they should appear in the urine in due course, if they are not absorbed they should appear in the faeces or be shown to be destroyed by the intestinal flora. The results of previous studies of excretion in man were conflicting, so CLARK and MACKAY began by repeating this work. The recommended therapeutic dose of rutin was 60–120 mg daily by mouth. CLARK and MACKAY gave normal volunteers single doses much larger than this—about 50 mg per kg of body weight—and could not detect any excretion of rutin or its metabolites in the urine, the same negative findings were obtained with methylated hesperidin chalcone, a related substance. A patient who had had a gastric resection was known to absorb and excrete in the urine the anthocyanin pigment of beetroot, which is chemically allied to rutin, but when this patient was given 1 g of rutin by mouth there was again no detectable excretion in the urine. In some volunteers the stools also were analysed, and even after these

massive doses the amounts of rutin recovered were insignificant. This observation was explained when it was shown that if rutin is incubated with human faeces in water it is destroyed. Experiments with rats and guinea-pigs confirmed that negligible quantities of rutin, citrin or other members of the group are absorbed from the intestine and excreted in the urine, but instead of being destroyed, as in man, the doses given to these animals could be recovered almost intact from the gastro intestinal tract. It will be difficult, therefore, to dispute the American verdict of "no conclusive evidence available to substantiate the claims advanced for these drugs."

The Making of Florence Nightingale

A NEW cost-accounting system for the Army Medical Services was put into action between 1860 and 1865. In 1947 the Select Committee on Estimates found that it was still working admirably, though systems installed in other departments during the past 20 years had been discarded. Who, they asked, had devised it? FLORENCE NIGHTINGALE, they were told. It was just one of the countless things that incomparable amateur threw off. How much influence she has had, and is still having, on our affairs will never be assessed, even in a detailed account of this close packed life. Mrs WOODHAM SMITH¹ has been unable to do more than indicate the pies in which she had a useful finger. We know that she cleared away an immense amount of rubbish in the Army Medical Department, that she was the first to give the soldier something more constructive to turn to, in his leisure, than the gun shop and the brothel, that she was the pioneer of sanitary reform in India (which she never visited) and that she gave some half dozen newly appointed Viceroy's their "Indian education" before they set sail, that she was a much consulted authority on hospital construction, that she wrote, mainly anonymously, great numbers of pamphlets on hygiene and public health, and a vast work, never published, on Army hospital administration, that she was an exponent of record keeping and statistics, and a member of the Statistical Society, and, of course, that she founded modern nursing. The maternal figure with the lamp is real enough (she even thought of herself as in some sense the mother of the dead at Scutari and the champion of their living brothers in the Army) but it is an abstraction which leaves out of account the powerful mind informed by years of first-hand observation and exact note taking, the prodigious memory, the ability to analyse great quantities of facts, the passion for figures, and a diligence far beyond the common.

Victorian England offered women no direct power all through her life she had to work through others—at Scutari through the doctors, and later through Ministers and other public men. Since this never seemed strange to her (and, indeed, saved her a deal of scuffling in the arena), she was the opponent rather than the advocate of women's rights. For she could never be brought to realise that her position was unique, indeed, it was among her more troublesome characteristics that she never thought herself out

of the ordinary, and she often scolded her helpers, not for their lack of equal powers, but for their unwillingness to take trouble.

In the famous letter of 1854, inviting her to take a party of nurses out to the Army hospital at Scutari, SYDNEY HERBERT wrote "There is but one person in England I know capable of organising and superintending such a scheme." He was right. She was, as Mrs WOODHAM SMITH puts it, a weapon uniquely forged for the purpose. But what had done the forging? Not long years of nursing training, certainly. Though she was already 34, her nursing experience—apart from that offered by occasional illness in the family or village—dated from only 4 years before and had been, we should now think, decidedly sketchy. In 1850 she had paid a visit lasting a fortnight to the 100 bed hospital of the Institution of Deaconesses, at Kaiserswerth, and in 1851 she spent a few summer months there working as a nurse. The rest of her training consisted in visiting and minutely observing hospitals, almshouses, and infirmaries in whatever part of Europe she happened to be at the time, in studying her notes, and in extracting principles from them. At last, only a year before she was called to the Crimea, she was appointed as superintendent (unpaid) of a small institution "for the care of Sick Gentlewomen in Distressed Circumstances", and there she completed—or developed—not so much her training as her single handed discovery of nursing.

This, though it was not the forging, proves the quality of the metal. Many natural gifts contributed to that quality: she was well-born, well educated, intelligent, beautiful, and endowed with a charm that was always to win others to follow her lead. Her family were much in society and as she grew up she moved among notable and responsible people. It seemed certain that she would marry well and live the life of a successful society woman, by deliberately choosing otherwise she unwittingly ensured that the metal should be thoroughly tempered—in the fires and waters of Victorian family disapproval. What holocausts, what cataracts these could be Mrs WOODHAM SMITH describes at length. Miss NIGHTINGALE knew at 18 that she wanted to nurse. For 16 years afterwards, until Scutari released her for a different feat of endurance, she bore the opposition, reproaches, and counter claims of her parents and sister, and, worse than all these, her own sense of guilt. All her life she was deeply religious, and for most of those 16 years she believed that in opposing her family she was failing in her duty to God. She strove to submit, to bear patiently the daily round of gossip and visiting, of listening to papa reading scraps from the newspaper, of arranging flowers and taking a little drive. It would not do, rebellion smouldered in her, and when the time came burned with a clear flame.

The patience she learned in those frustrating years stood by her. It gave her the strength, while men died neglected round her, to hold herself and her nurses in check until the resentful doctors would grant them the right to enter the wards, it taught her to endure the obstructions of such men as Sir JOHN HALL, chief of medical staff, who did all he could to ruin her work. (THOMAS WAKLEY, editor of *The Lancet*, had crossed swords with HALL a few years before, in the matter of a soldier who died after a

¹ Florence Nightingale. By CECIL WOODHAM SMITH. London. Constable. 1950. Pp 615. 15s.

flogging) For weeks the work she had come to do was withheld from her, she schooled herself to use her abilities in other directions. Thus she became "purveyor" to the Army, supplying—out of funds put at her disposal from England—drugs, surgical instruments, baths, hot-water bottles, and medical comforts from which the wounded were debarred by Army red tape and an obsolete system. In the end, as we know, she achieved her object, and changed the whole miserable scene of Army nursing, but she did it in the face of continual opposition.

There are limits to the amount of frustration the human spirit can bear, and we should nowadays say that she came back from the Crimea with a neurosis. But, like CHARLES DARWIN'S,² it was a neurosis curiously useful for the rest of us. DARWIN had to spend half his day resting in order to get through his work, Miss NIGHTINGALE had to work all day and half the night in order to rest at all. After the war everyone was ready for a holiday, she was not, she was burning for reform. The more her family and friends—even the devoted SYDNEY HERBERT—urged her to take a holiday the more restive she became, and at last she fell ill. That illness, with variations in intensity, was to last many years and serve her purposes exceedingly well. It seems to have taken the form of physical weakness, inability to eat, severe palpitations, breathlessness, insomnia, and fainting attacks—a collection of symptoms which, when no organic cause can be found, is always being given new names. That organic disease was absent in Miss NIGHTINGALE'S case seems clear from the fact that she lived to be 90, but throughout her middle years she and her friends believed that she was dying, and the end was expected at any time. This had many advantages: it enabled her to rest physically while she grappled with the mental toil she imposed on herself, it allowed her to refuse all invitations and to deny herself to any callers who might waste her time, it restricted her to the society of enthusiasts for her causes, and licensed her to drive them hard (was she not driving herself to her death?), and above all it protected her from her family. Any threat of a visit from her mother or sister provoked one of her "attacks", this was her only safeguard—not the less humiliating because it was unconscious—against a return of the old emotional tyranny. She came home from the Crimea in 1856, by 1857 she was a chronic invalid and hard at work.

Time alters patterns. In 1880 her mother's death finally freed the 60 year old Miss NIGHTINGALE from all demands except those of her own undeserved self reproach. But she began at last, slowly, cautiously, to savour her independence, and the generous nature which had so long expressed itself in great public causes was eventually able to flower in personal relationships with a wide company of friends, many of them young people. The prosperous Nightingale School of Nursing, founded at St Thomas's 20 years before, gave her active brain scope, the young nurses gave her warm affection and loyalty. Her health improved, she went about more, and the thin faced forceful witty invalid of the middle years became the buxom humorous old lady of the late portraits. Do we see there what nature intended her to be if

her family had been equal to her needs? But what then would have become of the passionate fighter? It is hard, in retrospect, to regret anything that went to the making of FLORENCE NIGHTINGALE.

Annotations

CULTURE OF MALARIA PARASITES IN VITRO

THE growth and development of living cells largely depends on their chemical and physical environment being correct. If the scientist know enough to provide and maintain such an environment, any cell or part of a cell could presumably be cultured in vitro for ever. Some organisms are less exacting than others in their requirements. Thus free living amoebae will flourish in a drop of dirty rain water, and fibroblasts from a chick embryo will multiply indefinitely in a simple salt solution with the addition of serum and embryo extract. But many parasites, such as viruses, rickettsiae, and some protozoa, normally grow only inside living cells and so are accustomed to a very special and complex environment which the biologist can imagine but cannot yet define or reproduce. Hitherto, none of these obligate intracellular parasites (except a few bacteria) have been cultivated outside their particular host cells. Now, however, Trager¹ has persuaded one of the more delicate of these parasites, *Plasmodium lophura*, the organism of bird malaria, to develop for several days outside the red blood cell in which it is accustomed to live.

As may be imagined, both the procedure and medium are highly complex, but the salient points may be simplified. *P. lophura* normally grows inside duck's red cells. The first step in its cultivation outside these cells is to free the parasites from the red cells as gently as possible, this is attained by hemolysing the red cells with specific antiserum. The parasites are received into a complex salt medium containing most of the known vitamins and growth promoting compounds, together with glutathione, hexose diphosphate, yeast adenylic acid, and cozymase, and having a high potassium sodium ratio. This is mixed with a concentrated extract of red corpuscles to supply the nutrients and labile enzyme systems to which the parasite is accustomed in its intracellular existence. The pH is adjusted to 6.75—i.e., slightly on the acid side of neutrality—and an atmosphere of air plus 5% CO₂ is provided. Apparently it is important to give the parasite some supporting physical framework to act like scaffolding, and this is done by adding gelatin, which at 39°C combines with the red cell extract to form a scum of the right density and structure. The other essential chemical constituents include adenosine triphosphate and sodium pyruvate. Throughout the manipulations great consideration must be shown to the parasites, and the fluid medium must be changed every 12 hours. By these means, Trager has maintained the development of all the parasites, outside their host cells, for at least two days. The first generation of parasites mature to schizogony, and new merozoites liberate themselves and begin the second stage of the cycle by developing into fresh trophozoites. On the third day most of the free parasites are still normal in appearance, but by the fourth day more of them are degenerate and by the fifth day there are very few normal parasites left.

We must conclude that Trager has not yet completely reproduced the complex environment existing inside a red cell. But his results would have seemed unbelievable a few years ago. This triumph of biochemical knowledge and technical skill will be an inspiration to those who are studying the intricate chemical and physical systems of living organisms in general, and of malaria parasites and red cells in particular.

EPIDEMIOLOGY OF DIPHTHERIA

DURING the late war diphtheria was pandemic in continental north west Europe. In North America, however, the long phase of exceptionally low incidence was undisturbed, and in Great Britain the perennial toll of the disease diminished during the period of its greatest prevalence on the Continent. To elucidate the causes of these diverse patterns, Prof J W McLeod, F.R.S.¹ (to whom the differentiation of the cultural types of *Corynebacterium diphtheriae* is due), has examined the various contributory factors during the years between 1926 and 1946. Urbanisation, as in Great Britain, begets a continuously high incidence, and, especially during epidemics, the parallel phenomenon of natural immunisation through subclinical infections. Further more, in war time the migration of civilians or infiltration of foreign armies from zones of severe epidemic diphtheria must be taken into account. But apart from these environmental factors, to what extent have prophylactic inoculation and the prevalent cultural type of *C. diphtheriae* controlled the development and course of epidemics?

In North America prophylactic inoculation has for many years been carried out on an immense scale, and this has undoubtedly been important in producing the very low incidence in that region.¹ Immunisation has likewise contributed to the fall in incidence in Great Britain from 1942 onwards. Nevertheless, before the late war Norway, Denmark, and Holland had a very low incidence to which inoculation contributed little or nothing, and McLeod believes that natural immunisation during epidemics played an important part. Why, then, should the incidence in these countries have risen to epidemic proportions during the war? The short answer is that virulent types of *C. diphtheriae* "appeared" and upset the parasite host equilibrium attained after infection with less virulent types. In Norway and Denmark, as in the U.S.A., gravis strains were absent or rare during the inter war phase of very low incidence, and in Amsterdam the mitis strain predominated for many years, until, during the war, intermedius and, later, gravis strains appeared and a formidable epidemic resulted. It seems possible that these virulent strains were introduced by German invaders, just as an isolated epidemic of gravis diphtheria in Halifax Nova Scotia, has been ascribed by some to the arrival of Norwegian sailors. On the other hand, McLeod shows that during the inter-war years "epidemic spikes" in British cities were commonly associated with a predominance of intermedius or gravis strains, and there is no reason to believe that these strains were imported. It may be, he suggests, that "several independent varieties of *C. diphtheriae* exist each of which produces a distinctive though similar type of disease", but because intermedius so often precedes gravis strains before and during epidemics, McLeod suggests that they may be a recurring cycle of evolution "in which the different forms described represent merely phases". Thus at fairly long intervals, under some unknown stimulus, mitis may mutate to intermedius, and thus, linked by a subtype, to gravis which, similarly linked, ultimately reverts to the mitis phase.

However this may be, it is clear from the experiences of Norway and neighbouring countries that gravis strains can break down the barrier of natural immunisation, and the Nova Scotia epidemic, the high incidence of diphtheria among American troops exposed to gravis infection in Europe, and the studies of gravis diphtheria in Gateshead and Dundee² show that prophylactic inoculation does not necessarily provide a sure shield against this strain. But whereas among the unvaccinated gravis infections often prove fatal, among the inoculated deaths are rare. McLeod "cannot over-emphasise"

this (Similarly, Hartley, Tulloch, and their colleagues³ insisted on the "paramount importance" of prophylactic inoculation in the reduction of mortality from gravis diphtheria.) McLeod believes that an immunisation-rate of 70-90% may prevent the development of a severe gravis epidemic, and that this is possibly the secret of the very long periods of negligible incidence in American and Canadian cities.

THE BRITISH LEGION VILLAGE

"Independence is the only real defence against disability," as the *Times*⁴ said not long ago. The British Legion have kept this principle constantly in mind, and nowhere more than in the village and reablement centre for the tuberculous which they founded near Maidstone twenty five years ago.⁴ Since then over 10,000 men and women disabled by the disease have either been reabled and passed out of the centre—many of them fit to return to normal industry—or have found homes in the village colony where they have contributed their share of the country's production in the workshops founded there to give them employment. There is nothing dilettante about these industries since the village was founded, in 1925, £1,270,000 has been paid out in wages, while the value of the industrial output has been £2,190,000. The main productive industries are carpentry, printing, and the making of fancy goods (by the severely disabled). But the village itself naturally provides many other occupations for reabled patients who are training for a return to ordinary life. Thus the engineering department is busy with reconstruction and improvements in the village property—putting in hot water systems, wiring for electrical equipment, and so on—and the building and maintenance department is continuously engaged in repairs, reconstruction, and painting and decorating for the industries and village. The transport department, with lorries, vans, and cars, can offer a good course of training for those who aim to become motor mechanics.

After the 1914-18 war a vocational training centre for tuberculous ex-Servicemen who had completed their sanatorium treatment was established at Preston Hall, the big Victorian mansion which presides over the village and nowadays houses the administrative centre. The village settlement grew up round it, and the original 50 beds for patients had increased, by 1948, to 926, some of them in three pavilions, built in the course of the years, some in the E.M.S. hospital set up in 1939 and attached to Preston Hall, and some in a convalescent home at Bournemouth and the Navland Sanatorium for Women, near Colchester. Instead of the one hostel and 25 houses, put up in 1926, the village can now boast of 136 houses or bungalows. It has its own village stores and post office, and a cafe registered as an industrial canteen and run by the catering department. In 1948 the hospital, sanatorium, and convalescent homes were transferred to the National Health Service, but the village and the reablement unit remained under the Legion. The Minister expressed his firm wish that all should still work as a unit and so they do.

The reablement side is very largely run for the tuberculous by the tuberculous of an administrative staff of 45 no less than 40 are recovered or recovering patients—a very great encouragement to newcomers. The village children live the same life as other village children—but have the strange privilege of being less likely (so the figures show) to catch tuberculosis than the common run. During the 1939-45 war 104 sons and daughters of tuberculous ex-Servicemen served in the Forces, and none of those who returned had contracted the disease.

The jubilee year of the village comes at a time when plans for further extensions are in the air, and indeed

rapidly coming down to earth. Relieved of the responsibilities of the hospital, sanatorium, and convalescent home, the British Legion can now direct their energies to the training and resettlement of the ex-Service tuberculous and they hope to offer apprenticeships for posts in normal industry commanding good salaries and prospects of promotion. Success in this project, they say, must depend on the support of every branch of the Legion, and all the other friends of this work.

CONTROL OF RABIES

THE administration of hyperimmune serum followed by a course of vaccine seems to hold great promise in the treatment of rabies in man, and in early trials satisfactory results have been obtained with avianised vaccine, containing active virus modified by passage in the chick embryo. A vaccine of high potency is also obtained when the virus is inactivated by irradiation with ultraviolet light. This was the opinion of the W.H.O. Expert Committee on Rabies when it held its first session in Geneva last April.¹ A field trial is to be made in Iran, where wolves still roam widely and severe bites from rabid animals are common. Discussing the control of rabies in animals the committee emphasised the value of annual vaccination of all dogs in enzootic areas, now that vaccines are more effective. It is hoped that W.H.O. will be able to carry out large scale field demonstrations of the value of regular immunisation. Furthermore, "experience has shown that the efficient organisation of a rabies control programme in an infected area is best accomplished by means of a central authority headed by a public health officer, preferably a veterinarian, who has full executive power and who devotes his full time to this work."

Other livestock bitten by rabid carnivores are unlikely to propagate the disease. Exposed animals can be safely slaughtered for meat within one week of the bite or after six months. The greatest risk is encountered, not through consumption of meat or milk from infected creatures, but by those who handle the live animal or the carcass.

ACUTE BENIGN PERICARDITIS

At the time of the year when upper respiratory infections abound, the onset of a pain in the chest does not always point to the heart. Yet it is in just these circumstances that acute non-specific pericarditis is apt to occur, and for the same reason this diagnosis is probably more often missed than made. This is partly the fault of medical writers, few of whom have given the condition more than scanty recognition.

The onset is usually acute, with pain, an initial pericardial rub, a raised erythrocyte sedimentation rate, and fever which may last for several days. Though the pericardial fluid is sufficient to alter substantially the cardiac X-ray silhouette, tamponade effects are not prominent, and therapeutic aspiration is seldom necessary. The fluid may be bloodstained but is sterile on culture. Typical but transitory electrocardiographic changes of pericarditis accompany the illness. Recovery is rapid—though occasionally there is a relapse—and chronic constrictive pericarditis does not follow. As Feder et al.² point out, the condition may be passed off as a cold or pleurisy, but when its symptoms are more severe and pain is dominant there may be difficulty in distinguishing it from coronary occlusion or some acute abdominal disorder. The pain of pericarditis, however, is often exaggerated by deep breathing, coughing, or motions of the trunk, or by swallowing, and other features which help to differentiate it from that of coronary thrombosis are the early incidence of a wide spread pericardial rub, an initial fever and raised E.S.R., the absence of abnormal Q waves and of reciprocal R-T

changes in leads I and III of the E.C.G., and the history in many patients of a pre-existing upper respiratory infection. Acute benign pericarditis is distinguished from acute rheumatic pericarditis by the absence of joint pains, a normal P-R interval in the E.C.G., and a shorter clinical course.³

At the recent International Congress of Cardiology in Paris H. B. Sprague and D. B. Carmichael described 50 cases observed during the last twenty years, concluding that the cause is possibly a virus infection, and at the same meeting W. A. Brams and M. Taubenhans quoted dramatic results with 'Aureomycin'. But Feder et al.² found that the cold agglutinin reactions were negative in their 5 cases, suggesting that if indeed a virus is implicated it is not the one responsible for primary atypical pneumonia. On the other hand, the similarity which the clinical course of acute primary pericarditis bears to that of acute pleurisy with effusion may suggest a common aetiology. Observations on Mantoux reactions and guinea-pig inoculations with pericardial fluid would be profitable lines in future research.

PREFRONTAL LEUCOTOMY

SINCE Mowbray first essayed destruction of the white fibres in the forepart of the frontal lobes in 1935, increasing attention has been directed to the results of an operation which, since it is directed at the brain, in the absence of gross organic disease, has aroused almost as much anxiety as it seeks to allay.

Reports of the results in small groups and in large groups, with this cut and that cut, are pouring into the medical and also the lay press, but in recent years their assessment has been complicated by wide variation in technique. One of the merits of a book by Dr Maurice Partridge⁴ is that it surveys 300 cases, all operated on by Mr Wylie McKissock with the same technique, and almost all followed up, six months, twelve months, and two years after the operation. Manic depressive insanity, depressions without mania, schizophrenia, and obsessional neurosis accounted for 273 cases.

Partridge's conclusions on the whole confirm those of others. Manic patients do badly, and so do patients who have had frank manic attacks operated on while they are depressed, depressives of good previous personalities do well, and so do obsessionals, even 5 atypical obsessionals did surprisingly well. It is less easy to summarise the results in 157 cases of schizophrenic illness: a sustained recovery in about a quarter of 35 cases with affective colouring, and in about a fifth of the cases with histories of remissions, is encouraging when one considers that operation almost always followed active therapy with insulin and electroplexy. A recovery rate of only 8% in cases without remission or affective colouring seems poor in comparison, but some of the remainder were much improved in conduct and therefore became less difficult to nurse, or were able to be discharged, though still psychotic. Partridge faces the fact that many could be described as psychopathic: this, in his view, does not prevent success, though it calls for keener aftercare. He admits that nearly all his patients showed some deficits (With some of the newer techniques such deficits seem to have been reduced.) On the other hand, in the relief of having the patient home again, relatives seem able to tolerate handicaps which—were affection absent—must give rise to dismay or chronic ill temper. The results in these 300 cases do not warrant uncritical enthusiasm, but their analysis offers evidence on which the standard operation can be judged.

Sir WILLIAM THOMSON, professor of medicine at Queen's University, Belfast, and a member of the General Medical Council, died on Nov. 20 at the age of 65.

the treatment of a particular patient is decided. The wishes and attitude of the patient of course greatly influence this decision.

Sometimes a meeting is devoted to discussion of a patient or family presenting peculiar difficulties. For the purpose of arriving at a constructive scheme of therapy the team may invite to such a conference the representative of an outside agency which is principally concerned—e.g., a medical specialist, a school medical officer, an expert in child guidance, a probation officer, a clergyman, a National Assistance officer, or a member of a local voluntary social organisation.

RECORD SYSTEM

In the record system which has lately been put into operation there are five elements

1 *The registration card*, which is completed (usually by the almoner) when the patient first registers, and which shows name, age, date of birth, identity number, date of joining the practice, and previous doctor.

2 *The patient's medical record*—This consists of a quarto manilla folder containing the actual medical case sheet and any relevant medical documents (e.g. specialists' and laboratory reports) which are in use. The medical case sheet is merely the National Health Service medical record card (form E.C.8) slightly modified and printed on quarto paper. The manilla folder is printed on both sides. On the left (p. 1) are recorded the patient's name, address, occupation, age, birth rank, and previous medical history, with space for the doctor to record the results of systematic physical examinations. The right-hand side (p. 2) is intended for a summary of the patient's illnesses after he joins the practice.

3 *The family record folder*—This folder, of foolscap size is filled numerically according to the family index number. It contains all the family's records together with any further information about each member which is not actually in use in the individual's medical record folder.

4 *Records made by the nurse* (e.g., antenatal records or records of children who attend the baby clinic or child welfare sessions) are at first filed in the individual's medical record folder. After they have served their purpose they are filed separately but an indication that the record exists is given on p. 1 of the individual's medical record card. The almoner keeps her own record of any work she does with a family. This also is filed separately but the existence of the record and the nature of information it contains is also indicated on p. 1 of the individual medical record card.

5 *Referral Cards*—When a member of the team has been allotted a specific duty (particularly at the case-conference) a small card is made out indicating the job to be done and the person who is to do it. He or she enters relevant data on the card which may itself act as a method of recording. It may show, for example, how often a particular item of service was required.

TEACHING

We accepted our first students in October, 1948, and hitherto 62 have been given a three month course. At Edinburgh, each 'year' has on average 200 undergraduates. At present we can take no more than 10 or 12 per term—up to, say, 40 a year—and applicants, who must be in their last or penultimate year of training, have always been more numerous than vacancies.

In undergraduate teaching our primary concern is to illustrate the social aspects of health and sickness. If, in the process, we have to digress to discuss a technical point in clinical diagnosis and treatment that is incidental.

The student's instruction is in three phases. First, he observes the family doctor at work. Secondly, he is introduced by the doctor to a number of patients as the doctor's (student) assistant, and as an apprentice takes over delegated responsibility for diagnosis and treatment. Lastly, by means of seminars and case-conferences, he gains insight into the significance of what he has seen and heard in the course of his practical work.

The students attend as a group once a week. In addition, each student is allotted a particular consulting hour once a week during the ten-week term. Only one student at a time is with the doctor in the consulting-room, where he quickly learns to fit into the background. He is introduced to the patient as a senior student giving the doctor clerical help while at the same time being under instruction. The patient knows that he has a right to see his doctor in private, and if the patients insist, the doctor will ask the student to withdraw or arrange to interview the patient at another time. This seldom happens, but causes no embarrassment when it does. For his first few sessions the student is mainly an observer, but he gradually comes to know and to be known and finally accepted by a number of patients. By mid term he has a small "practice" of some half dozen patients, by whom he is identified as the doctor's assistant and he engages, under supervision, in the diagnosis and treatment of these patients in their own homes and at the consulting room, having all the resources of the team at his disposal. A second consulting room and a side room are available to him at the dispensary, so that he can see his own patients by appointment at their and his convenience. From this small group he selects a family to present at the end of term.

At the first of the group meetings—i.e., on the first day of term—the students are reminded of the ethics which govern the doctor-patient relationship and of their privileges and responsibilities as medical students. They are introduced to the staff and given a brief account of the family-doctor team. At the second meeting we deal briefly with administrative topics, such as certification and prescribing, relating mainly to the National Health Service Act. At the next meeting, usually taken by the almoner, the students are introduced to some of the more important statutory and voluntary social agencies. By this stage the students themselves are beginning to provide questions for discussion, and an attempt is usually made to contrast hospital and general practice. At mid term the students are provided with the outline of a scheme of social case-taking which is illustrated by the completed case-report of one of their predecessors. In the remaining sessions each student presents to the group an account of the medical and social circumstance of an entire family which he has treated. He is invited not only to outline the medical and social therapy he has been able to prescribe but also to catalogue the items he would like to prescribe were he omnipotent. All the staff are present at these seminars and are ready to answer questions and to illustrate and amplify the major points evoked by the discussions.

THE FAMILY CLUB

The dispensary premises include a moderate sized hall, capable of seating in comfort some 120 people, which has a fitted stage and a cinema screen. Originally this was built and used as a lecture room for medical and pharmaceutical students.

In January, 1949, using a 16 mm sound projector and films borrowed from the Central Film Library, we began a series of monthly film shows to which all our patients were invited. The films were documentaries prepared for popular health propaganda by the Ministry of Health, the Ministry of Information, and the Central Council for Health Education. We also showed films illustrating the development of community centres, including the Peckham documentary *The Centre*. At these meetings discussion and questions were invited.

The response was slow at first but in April 1949 half a dozen patients volunteered to constitute the nucleus of a social club. Within three months the club had been formed, had adopted a constitution, and

The practice is on the fringe of one of the most overcrowded slum areas of the city. Problem families, the very poor, and residents of nearby common lodging houses, on arriving in the neighbourhood, will tend to gravitate towards the practice. Almost all other recruitment will be by the transfer of patients from the lists of other doctors in and around the area. So far, while keeping very strictly within the bounds of ethical propriety, we have simply accepted any patient who wishes to join or transfer to our list. Despite the competitive element inherent in the capitation system of payment, the growth of the practice has not so far embarrassed our relations with local practitioners, with whom we might be said to be competing unfairly.

This, however, has been one of the many factors in estimating the optimum size of the practice. It has been decided that the number of patients should never exceed 2000 and the optimum be rather smaller. Should we now deliberately select those for inclusion in the list from the further applications received? The statistician's concept of a perfect vertical cross section of society is purely theoretical, and any attempt to create such a sample with 2000 people registered with the same general practitioner would be futile. At the same time there are advantages in having access to a reasonably representative community, and it is therefore proposed that in filling the remaining vacancies we should have regard to such factors as age, sex, marital status, housing, and occupation. The one *sine qua non* is that in discussing our findings (e.g., morbidity indices) we should always know "who is present"—i.e., the population at risk.

Apart from geographic considerations, the only other major factor influencing further recruitment is that for traditional and ethical reasons we must always accept the chronic sick, the very poor, the irresponsible, and the nomads who have difficulty in getting on to the list of already overworked doctors. Though the practice will inevitably be weighted as far as these groups are concerned, it will be a much more heterogeneous community than the clientele of the dispensary before 1948. Under the old régime, the dispensary gave a personal service to individuals. It is hoped that eventually the practice will include, for the purposes of long term studies, some 400 complete families.

STAFF

In staffing the practice the assumption has been that it is no longer possible for one doctor to provide his patients with a complete service. With increasing specialisation final diagnosis and treatment rests increasingly often with a hospital department, and similarly in the social services the patient is referred to one of an ever increasing number of specialised agencies, about which the general practitioner often knows little and over which he seldom has any control.

Under the Montefiori system in New York, the hospital consultant, reinforced by paramedical and social workers, goes out from the hospital into the patient's home, carried to its logical conclusion, this method would in the end annihilate general practice. Our approach is the exact antithesis of this. We are attempting to reinforce the general practitioner with additional skills and techniques, including the "use" by him of consultants, so that more and more the investigation, assessment, diagnosis, or treatment of the patient is co-ordinated and controlled by him. In this practice the family doctor has been replaced by a team, the aim is that while each member should practise a different skill, all should be integrated to function as a single unit. This family doctor team tries to treat people—or rather families—rather than diseases. The core of the team is the doctor and a social worker (almoner). It also includes a nurse (who has additional qualifications and experience in midwifery and local authority health

visiting), but the nurse, while she has a special contribution to make, uses a skill that is essentially the same, except in degree, as that of the doctor. The almoner, on the other hand, does work outside the scope of both doctor and nurse.

ROUTINE

Except in an emergency, only those registered as patients of the practice are seen at the dispensary. Consultations are held twice daily except on Sundays. Requests for home visits are received either at the dispensary or at the doctor's house. All domiciliary visits are paid, in the first instance at least, by the doctor himself. The consultations at the surgery are conducted by the doctor or his assistant. At the morning surgery the nurse is always present. She also has a daily session in the late afternoon, at which she does dressings, gives injections, and sees patients referred to her by the doctor. For the rest of the day she acts as a district nurse and health visitor (as far as our own patients are concerned), doing domiciliary visits. The almoner sees patients during the morning consulting hour and at other times by appointment. The pharmacist attends during the consulting hours. The chiropodist and the dentist attend twice weekly to see patients by appointment.

The midwifery arrangements are as follows. Because of housing, most patients are delivered in hospital. If a patient cannot or will not arrange to be delivered in hospital she is delivered at home by the doctor, the midwife being supplied by the usual arrangement with the local authority. (As our nurse is engaged in general nursing she cannot be employed as a midwife or maternity nurse.) Whether the expectant mother is to be delivered at home or in hospital, we undertake antenatal supervision, even if, in the case of women to be delivered in hospital, this causes some duplication. One afternoon session is held weekly with the doctor and nurse present, when appointments are made for routine antenatal supervision, postnatal examination, and advice. As soon as the child is born, the nurse is notified and the mother is invited to attend a mother and baby club which is held on one afternoon a week. This fulfils the function of a child welfare clinic, except that only our own patients attend, routine weighing, examination, vaccination, and immunisation are offered. The nurse always attends these sessions, and the doctor is available.

THE DAILY CONFERENCE

A staff meeting is held daily (except for Sundays) and is always attended by the two doctors, the nurse, and the almoner. This, in my view, is the most important single item of our routine. The primary object of this meeting is to integrate—or rather to create—a team by means of joint discussion. The conference, which lasts on average from a half to three quarters of an hour, has two facets. First, each member gives a brief account of his or her contacts with patients or with medical or social agencies. Secondly, there follows a discussion of any problems arising from this exchange of information, along the lines of a case conference. The doctor acts as chairman, and each member is free to give his opinion or comments. The object is to review all that is known of the medical and social circumstances of a particular patient against his family background, to reach a working diagnosis of the family situation, and to evolve a régime of therapy which will satisfy the patient's immediate needs and will at the same time be sufficiently well defined to ensure that the team works to a common pattern in future contacts with other members of the family, and yet sufficiently elastic to allow of modification in the light of new knowledge about the family or changes in its circumstance. At this conference the role of each member of the team in

the treatment of a particular patient is decided. The wishes and attitude of the patient of course greatly influence this decision.

Sometimes a meeting is devoted to discussion of a patient or family presenting peculiar difficulties. For the purpose of arriving at a constructive scheme of therapy the team may invite to such a conference the representative of an outside agency which is principally concerned—e.g., a medical specialist, a school medical officer, an expert in child guidance, a probation officer, a clergyman, a National Assistance officer, or a member of a local voluntary social organisation.

RECORD SYSTEM

In the record system which has lately been put into operation there are five elements

1 *The registration card*, which is completed (usually by the almoner) when the patient first registers, and which shows name, age, date of birth, identity number, date of joining the practice, and previous doctor.

2 *The patient's medical record*—This consists of a quarto manilla folder containing the actual medical case sheet and any relevant medical documents (e.g., specialists and laboratory reports) which are in use. The medical case sheet is merely the National Health Service medical record card (form E.C.8) slightly modified and printed on quarto paper. The manilla folder is printed on both sides. On the left (p. 1) are recorded the patient's name, address, occupation, age, birth rank, and previous medical history, with space for the doctor to record the results of systematic physical examinations. The right-hand side (p. 2) is intended for a summary of the patient's illnesses after he joins the practice.

3 *The family record folder*—This folder of foolscap size, is filled numerically according to the family index number. It contains all the family's records, together with any further information about each member which is not actually in use in the individual's medical record folder.

4 *Records made by the nurse* (e.g., antenatal records, or records of children who attend the baby clinic or child welfare sessions) are at first filed in the individual's medical record folder. After they have served their purpose they are filed separately, but an indication that the record exists is given on p. 1 of the individual's medical record card. The almoner keeps her own record of any work she does with a family. This also is filed separately but the existence of the record and the nature of information it contains is also indicated on p. 1 of the individual medical record card.

5 *Referral Cards*—When a member of the team has been allotted a specific duty (particularly at the case conference) a small card is made out indicating the job to be done and the person who is to do it. He or she enters relevant data on the card, which may itself act as a method of recording. It may show, for example, how often a particular item of service was required.

TEACHING

We accepted our first students in October, 1948, and hitherto 62 have been given a three month course. At Edinburgh, each "year" has on average 200 under-graduates. At present we can take no more than 10 or 12 per term—up to, say, 40 a year—and applicants, who must be in their last or penultimate year of training, have always been more numerous than vacancies.

In undergraduate teaching our primary concern is to illustrate the social aspects of health and sickness. If, in the process, we have to digress to discuss a technical point in clinical diagnosis and treatment, that is incidental.

The student's instruction is in three phases. First, he observes the family doctor at work. Secondly, he is introduced by the doctor to a number of patients as the doctor's (student) assistant, and as an apprentice takes over delegated responsibility for diagnosis and treatment. Lastly, by means of seminars and case conferences, he gains insight into the significance of what he has seen and heard in the course of his practical work.

The students attend as a group once a week. In addition, each student is allotted a particular consulting hour once a week during the ten week term. Only one student at a time is with the doctor in the consulting-room, where he quickly learns to fit into the background. He is introduced to the patient as a senior student giving the doctor clerical help while at the same time being under instruction. The patient knows that he has a right to see his doctor in privacy, and if the patients insist, the doctor will ask the student to withdraw or arrange to interview the patient at another time. This seldom happens, but causes no embarrassment when it does. For his first few sessions the student is mainly an observer, but he gradually comes to know and to be known and finally accepted by a number of patients. By mid term he has a small "practice" of some half dozen patients, by whom he is identified as the doctor's assistant, and he engages, under supervision, in the diagnosis and treatment of these patients in their own homes and at the consulting room, having all the resources of the team at his disposal. A second consulting room and a side room are available to him at the dispensary, so that he can see his own patients by appointment at their and his convenience. From this small group he selects a family to present at the end of term.

At the first of the group meetings—i.e., on the first day of term—the students are reminded of the ethics which govern the doctor-patient relationship and of their privileges and responsibilities as medical students. They are introduced to the staff and given a brief account of the family doctor team. At the second meeting we deal briefly with administrative topics, such as certification and prescribing, relating mainly to the National Health Service Act. At the next meeting, usually taken by the almoner, the students are introduced to some of the more important statutory and voluntary social agencies. By this stage the students themselves are beginning to provide questions for discussion, and an attempt is usually made to contrast hospital and general practice. At mid term the students are provided with the outline of a scheme of social case-taking, which is illustrated by the completed case report of one of their predecessors. In the remaining sessions each student presents to the group an account of the medical and social circumstance of an entire family which he has treated. He is invited not only to outline the medical and social therapy he has been able to prescribe but also to catalogue the items he would like to prescribe were he omnipotent. All the staff are present at these seminars and are ready to answer questions and to illustrate and amplify the major points evoked by the discussions.

THE FAMILY CLUB

The dispensary premises include a moderate sized hall, capable of seating in comfort some 120 people, which has a fitted stage and a cinema screen. Originally this was built and used as a lecture room for medical and pharmaceutical students.

In January, 1949, using a 16 mm sound projector and films borrowed from the Central Film Library, we began a series of monthly film shows to which all our patients were invited. The films were documentaries prepared for popular health propaganda by the Ministry of Health, the Ministry of Information, and the Central Council for Health Education. We also showed films illustrating the development of community centres, including the Peckham documentary *The Centre*. At these meetings discussion and questions were invited.

The response was slow at first, but in April, 1949, half a dozen patients volunteered to constitute the nucleus of a social club. Within three months the club had been formed, had adopted a constitution, and

had begun to hold regular meetings in the hall. The aims of the club are

1 To further the well being of its members, to promote family health, and by common effort to foster a community spirit

2 To manage and maintain a community centre

3 To provide social, educational, and cultural activities, both indoor and outdoor, among its members

The development of the club has been slow for two main reasons. First, only patients can be members, the staff may participate, but may not have executive authority. Secondly, the club, although it has the hall free of rent, needs funds for its development. This is one of the activities to which the board of managers will be able to lend material support when their legal position has been clarified. Hitherto the club's activities have included a weekly social (average attendance 40-50), a boys' section (5-15 years) and a girls' section (5-13 years) each of which has met once a week during the winter, two motor coach outings, a children's Christmas party and an entertainment for some 120 old people on the club's roll, arranging for members confined to bed at home or in hospital to be visited, and running an adult beginners' class in Scottish country dancing. Members of the club arrange to brew tea for the mothers during the baby clinic sessions.

Although we have in fact no more than the outline of a club, the few really active patient members will almost

certainly keep the notion alive until expansion is possible. The strength of the movement is due to members being allowed to manage their own affairs, make their own mistakes, and experiment. We hope that the club will enable us to keep in touch with "patients" requiring care and attention, and that it will in fact become a family club after the fashion of Peckham, giving the way to systematic periodic family health overhauls.

SUMMARY

A general practice has been developed by members of a university department—two doctors, an almoner, a nurse, and a dentist.

In this practice an attempt is being made to bring together all the necessary skills and to integrate these in such a way that the whole person is treated.

A limited number of senior medical students are enabled to serve an apprenticeship.

It is a pleasure to acknowledge my indebtedness to Prof F A E Crew, F.R.S., head of the department, without whose inspiration and support the work could not have been undertaken. My thanks are due to my departmental colleagues and particularly to the following who have worked hard and patiently with me in the practice: Jane E Paterson M.A., Gwen Padfield, S.N., W J Abel, M.D., and J N Mansbridge, M.D. Mr B Woolf, R.D., has given much helpful advice on the design of records. I must also acknowledge the co-operation, which I have enjoyed from the beginning of the managers of the Royal Dispensary, one of whom, Mr Eric Knott, M.R.S., has acted as our honorary apothecary.

AN AID FOR SUPINE BED PATIENTS

J J SUMNER

M.C., M.D. Durb.

CHIEF ASSISTANT, HAREFIELD HOSPITAL, MIDDLESEX

ADULT patients being nursed in a complete supine posture on a Jones spinal frame or a plaster of paris posterior shell for long periods experience difficulty and frustration in reading, writing, washing themselves, and communicating with their neighbours. To hold heavy books is tiring for the arms, and they begin to demand more and more pillows under the head. The neck flexion which results may make an even longer period of immobilisation necessary.

An apparatus developed at Harefield Hospital, and illustrated in the accompanying figures, consists of a permanent adjustable steel book support, writing table, and toilet shelf with a large mirror. Except for

the mechanism fixing it to the bed head, the whole apparatus can be adjusted and manipulated with ease by the patient, who quickly finds it indispensable. The mirror and the combined support are mounted, independently of each other, on the adjustable horizontal bar, which can be rotated on the vertical bed attachment. Tensioned ball and socket joints allow a wide range of movement of both the mirror and the support, which is adjustable to all sizes of books. A copy of *Gray's Anatomy* can be read as easily as a Penguin. Easily mastered finger screw locking and sliding extensions enable the patient to change from one book to another. The shelf for toilet accessories can also support a book, or can be folded back when the support is closed down for writing. A touch of the finger swings the apparatus to the side of the bed, out of the way, when the patient is receiving nursing attention.

All patients being treated for spinal tuberculosis at Harefield are now using this combined reading, writing, and toilet aid, and consider it satisfactory. It is obtainable at 10 guineas from the inventor, C D Inventions, 9, Bridge Street, Westminster, London, S.W.1

GENERAL MEDICAL COUNCIL

OPENING the 178th session of the council last Tuesday, Prof DAVID CAMPBELL, the president, spoke with deep regret of the death of two former members of the council, Dr Edm Matthew and Lord Hacking, and of two active members, Prof W T Dilling and Sir William Thomson. By retirement the council had lost Prof J W Bigger, Prof Matthew Stewart and Lord Moran. As new representatives he welcomed Dr Russell Brain (Royal College of Physicians), Prof J W McLeod F.R.S. (University of Leeds), Mr J T Morrison, F.R.C.S. (University of Liverpool), Prof D S Torrens (University of Dublin), and Prof Hilda Lloyd (Royal College of Obstetricians and Gynaecologists). Though the late Dr Christine Murrell had been elected as a direct representative in 1933, Professor Lloyd was the first woman to undertake the full duties of membership of the council. "It is a happy coincidence that at a time when in the field of medical education the responsibility of the council is extended beyond the undergraduate into the postgraduate or post-qualification stage, the presidents of the three Royal Colleges in England are numbered among their members."

On July 25 continued the President, the Medical Act, 1950, received the Royal Assent. In the achievement of this Act his predecessor, Sir Herbert Eason, had played the paramount part, as was recorded by the late Lord Hacking in the House of Lords when he said of Eason:

"For many years he inspired his colleagues with his enthusiasm for the general welfare and integrity of the profession in which he was such an outstanding figure. He laid well and truly the foundation stone of this Bill, and was the chief bulwark of the edifice. It is sad that he could not see the completion of his work. I would pay my humble tribute to the memory of this remarkable man under whom I sat for a period of about ten years."

In his presidential address last May, Professor Campbell had outlined the main provisions of the Bill as it was passed by the House of Lords, and he now completed the story by mentioning the principal amendments made by the House of Commons, "where the Minister of Health was in charge of the Bill and laid us under a great obligation to him by one of his most masterly, if not one of his most masterful, displays of Parliamentary accomplishment."

The order of the Privy Council approving regulations of the council by which the period of employment in a resident medical capacity in one or more approved hospitals or institutions is to be prescribed, was made subject to approval of the draft of the order by resolution of each House of Parliament, colloquially known as an affirmative resolution.

I have reason to believe that some apprehension may still exist that the draft of the order may be laid before Parliament prematurely. Any such apprehension should have been removed by the explicit assurance of the Minister that

this is not going to be sprung upon the student immediately. It is going to take between a year and two years to make these arrangements, and members of the Education and Examination Committees and the council as a whole who are being invited to intimate consideration of the arrangements at this session will be under no illusion about their complexity or the time it will take to complete them.

In the disciplinary provisions of the Bill the scope of the rules to be made by the Medical Disciplinary Committee was extended in order to secure that matters should not be referred to the committee until they had been investigated by a specially constituted committee of the council, which would in effect be the Penal Cases Committee. It would be secured that any member of the council who acted in a case as a member of the Penal Cases Committee would be debarred from acting in the same case as a member of the Medical Disciplinary Committee—an exception being made for the president.

The acceptance of this amendment by the Minister on the simple ground that the idea is that those who have already taken part in screening have a tendency to pre-judge was the last word in a lengthy and ardent discussion of the proposal extending back to the preliminary stages of the preparation of a Bill. It would ill become the person who for the time being holds the office of president to discuss the

certificate of immunity from bias which Parliament has thus granted to him and it would not be fruitful to seek for the rationale of the protection against bias in reality or even in appearance, against which it has been thought right to protect other members of the council who might have served in the dual capacity. Our business is to accept cheerfully the decision of the Legislature and to make it work. I doubt not that we shall be able to man both committees as separate organisations.

The King's Speech on Oct 26 referred to recent progress in the consolidation of statute law, and the President was reminded of Sir Herbert Eason's proposal five years ago that suggestions should be prepared for the consideration of the Government should they find themselves disposed to consolidate and amend what must be so treated if a single and intelligible Medical Act is to be made available for the public good. Professor Campbell hoped that this far-sighted aspiration would also be realised at no distant date.

It had been intended that the council should be invited to appoint the Medical Disciplinary Committee and a Legal Assessor or Assessors to the committee. This would have enabled the committee at this session to settle a draft of rules as to their procedure and to enter into consultation on the draft. "The ultimate object was and is to enable the appointed day for the transfer of the disciplinary work of the council to the committee to be fixed in such time that all new cases will be heard by the committee in May, 1951." Unfortunately, however, the committee could not be appointed at this session, because the Act required that it should include at least two lay members of the council and the two such members additional to Lord Nathan who were to be nominated by His Majesty with the advice of the Privy Council had not yet been nominated. In these circumstances it would be the duty of the council to meet again in February 1951.

AU CONGRÈS MONDIAL

(FROM A CARDIOLOGICAL CORRESPONDENT)

THE affair began in the plane its occupants travelled in various moods. The American pair settled in the front seats, with the *New York Times* and a fashion paper, and paid little attention to the scenery or the information that the plane was now passing Dieppe. After all, they were used to long hops across the United States and had just crossed the Atlantic in eighteen hours. The Canadian had done all this voyaging and more he told us, and was inclined to be critical of the small size and low speed of the plane. Apart from a sprinkling of doctors and their wives—some airborne for the first time—only three other passengers are noteworthy: the child flying to France to join her parents for the holidays, the green man, and the lady doctor who being persuaded to travel by air, had taken the precaution of making a trial flight with Aer Lingus—for Aer Lingus has not had a flying accident. Each of us had an individual attitude towards the plane with its occasional bumps in the westerly gale, each had individual objectives. The only true international was the green man in pursuit of business in America, Europe, and Asia, who had been airsick in every civilised or semi-civilised country of the world. By the time Le Bourget was sighted, the green had become that of incipient jaundice.

Paris beneath its infinite variety is really the same efficient with baggage exact with bargaining exacting with rights, courteous with duties intolerant of strangers and their ignorance of local customs. The three lines of traffic charging up the boulevard take no heed of the three lines charging down in the opposite direction, or of the intrepid one in the seventh line who tries to thread his way through relying on a maximal acceleration instantaneous braking, and masterly judgment—the supreme individualist. Passing lights appears to be a minor matter with the gendarmes, for the drivers themselves know the danger the drivers take care of themselves.

Paris and French! Paris so suitable for comfort, for food, for sight-seeing. The Seine and its bridges, the wide.

streets, the great buildings set out in carefully tended gardens, Notre Dame, the Louvre, the spectacles at the Palais de Chaillot, the excursions to Versailles, to Chantilly, to Fontainebleau, the Sorbonne, so accessible, its theatres so numerous that two international congresses can be held simultaneously and without interference with each other.

Paris and French! Why choose French, which is now no longer the language of polish and diplomacy, which is almost unknown to the Anglo Saxon world and is mispronounced so badly by the Italian, Spanish, and South American peoples? How can the nations communicate with each other lacking an international language?

* * *

Our French hosts had prepared the site admirably, had inaugurated the congress with supreme success in the presence of two most important members of the government, had put in presidential and vice presidential chairs men of years and of most honoured names, and then, like the gendarmes on the boulevard, had left the individual to manage for himself his affair.

The decoration of the ceilings of the theatres where the sectional meetings were held was of museum status, but the narrow, hard seats with straight backs, the inadequate acoustics, the negligible ventilation, the movement of uncomfortable auditors, the close proximity of the noisy chatter of the assembly court, and the fickle lights. There appeared to be five lanterns, two epidiascopes, and one cinema projector, with two operators between the five sectional theatres. The lanterns appeared to have only one set of slide holders of each dimension, and much time was lost in getting the operator and his slide holders. It appeared too that there was no standard size for lantern slides laid down, or regular means of labelling. Thus many slides would not fit the holder, or were placed sideways or upside down, or contained so much data as to be unintelligible and inexplicable. Too often the performance was unrehearsed and the result comic.

The quality of the communications varied between the highest standard and fatuity, unfortunately, among a heterogeneous mass of unknowns there can be no seeding and no elimination. National characteristics became evident in delivery. The Frenchman had prepared a complete, rounded, and logical exposition which he delivered at a rapid pace and often in an undertone, intent on getting through his masterpiece in the time allotted. Italians and Spaniards read at speed French translations of their views, nose to paper, with atrocious accent. The Mexicans were good, they came as a team, each had at least one language other than his own, they sat together and were ready then to take up points in the discussion raised in any of the four official languages.

Surely there might be an arrangement that eight of the ten minutes should be used to give an outline of the main points of the communication followed by two minutes of summary in French and in English. This summary might be handed to an official interpreter to deliver, then it would not be made unintelligible by indifferent accent. There is much to be said for our insistence that communications must be spoken and not read.

At times an interpreter was provided, but he was often non medical and thus unable to give clarity to the points raised. On one important occasion there was no one who could reconcile the issues between an Englishman, a Frenchman, and an Italian. The best mutual interpretation was voluntary, and one whole session was much enhanced in importance and value by an Italian professor who summarised each speaker's words in French and in English.

* * *

The value of an international congress lies in bringing workers in the same field of medicine together from all parts of the world, in attempting to standardise methods so that workers throughout the world may use the same notation and mean the same thing, and in seeing and hearing men from other countries submitting their views and opinions.

Meanwhile some memories will remain the profoundly significant opening address of the aged president, Professor Laubry, with its insistence that in spite of all the help obtained by instrumental methods these must be subsidiary to examination and care of the patient himself and the clinical aspect, the witty and far-sighted allusion of M. le Ministre de la Santé Publique at the banquet, the cordial reception and attentive hearing given to Dr. Helen Taussig for her communications on the treatment of congenital heart-disease, the admirable collection of portraits of authors and copies of the works of those who had established cardiology, beginning with William Harvey and ending with Thomas Lewis, the masterly appeal of Paul D. White for world-wide research on the cause and management of heart-disease, even the small terminal vignette by the Stockholm professor, Björck, on the social consequences of cardiovascular disease in Sweden, a sound early contribution, all in the unique setting of Paris, Lutetia the lovable, in her infinite variety.

A NEW SCIENCE CENTRE

THE Lord President of the Council has announced that we may look forward to having a national science centre in London on a site to be chosen early next year. It will be some years before the Minister of Works can build such a centre, but a start will be made as soon as resources can be found. Within the new centre accommodation will be built for the Royal Society and for other leading scientific societies with their special libraries, most of which are now severely cramped in the rooms provided for them by the Government about 100 years ago in Burlington House or in other inadequate accommodation. The centre will also include the Patent Office and its library (which will be modernised and extended as a reference library on science and technology), the Department of Scientific and Industrial Research, and other Government scientific organisations.

Medicine and the Law

Varicose Veins and Military Service

IN deciding how far disabilities are attributable to (or, alternatively, have been aggravated by) war service the series of war pension appeals is assembling medico-legal material of varied interest. The case of Wallbridge v. Minister of Pensions, heard on Oct. 12 by Mr. Justice Ormerod, the "nominated judge" for this purpose in succession to Mr. Justice (now Lord Justice) Denning, concerned the disability of varicose veins. The appeal tribunal had decided that the condition was not attributable to, although it was in fact aggravated by, war service. The learned judge dismissed an appeal from this decision.

The appellant enlisted in the R.A.F. in April, 1939, at the age of 50, and at his medical examination was passed as grade I with no record of any varicose condition. When his service began in the following September, he was employed in plotting the position of aircraft. In the following March varicose veins were diagnosed with a previous history of varicose conditions in the left leg recurring at intervals. On his discharge in 1945 he applied for a pension, but the tribunal held that the condition existed before his service began. He was awarded a pension on the basis that the condition was aggravated by, but not attributable to, war service.

War pension cases arise on facts which are often too special to make judicial precedents. In the Wallbridge case reference was made to the previous case of Wills v. Minister of Pensions, decided a year ago.

Mr. Wills suffered from varicose veins shortly after joining the service. As there was a question of predisposition or congenital causes, the case was remitted to a tribunal and the opinion of an independent medical expert (Sir Ernest Rock Carling) was obtained. The latter reported that the plea that wearing heavy boots caused the condition was untenable. Marching, he said, was not a cause, prolonged standing was undesirable where

there was a varicose tendency, but it was not in itself an efficient cause. If either were in fact a cause of varicose veins, "the ranks of the Army would be riddled with cases." He considered that the varicosity was not attributable to war service, there was inherent weakness of the vein before war service, the varicosity arose during war service but was not aggravated thereby.

The Medical Services Division of the Ministry gave a further opinion, quoting several recognised medical authorities. The consensus of medical authority, stated the opinion, is that varicose veins are related to a congenital and inherited weakness of the walls of the veins and deficiency of their valves. Marching in heavy boots or the wearing of anklets would not produce varicose veins. The Ministry maintained the view that there was "a real preponderance of probability to the exclusion of reasonable doubt" that Mr Wills's disability arose independently of his service and was not aggravated thereby. The appellant's solicitors submitted further medical reports and the independent medical expert expressed a further opinion thereon. He noted the impression that some shop girls develop varicose veins, but there was no statistical evidence that the number was greater among those standing at the counter than among those in the counting house or among men who stand all day at machines. Return of blood through the veins was largely effected by the contraction of the muscles surrounding them, walking or marching, as such, was an advantage rather than a detriment. The superficial veins are not supported by muscles, functional inefficiency between the deep and superficial veins, caused by inherited defect, allows an incommensurate varicosity to develop as a man gets older and the vessel walls become less elastic. The course and the failure of operative treatment in Mr Wills's case made it clear that he suffered from such a valvular deficiency.

The tribunal held that war service did not cause Mr Wills's varicose veins, the injurious process had begun years before, there was a family history, the condition was congenital. The Ministry having discharged the burden of proof on the issue of attributability to war service, the appeal on this point was disallowed. On the issue of aggravation by war service the tribunal could not at first make up its mind, later it gave Mr Wills the benefit of the doubt, being unable to say that military service played no part in causing the deterioration.

On the Wallbridge appeal the judge interpreted the Wills case as establishing that if a man suffered from varicose veins, or if they became manifest during war service, it was difficult for a tribunal to hold them attributable to war service unless there was some evidence of a supervening cause other than the ordinary conditions of war service. In the absence of such supervening cause ordinary service conditions could not be regarded as causing varicose veins although they might aggravate the disability.

The ailments considered in connection with claims for war pension range from Hodgkin's disease, Parkinson's disease and diabetes mellitus to muscular strain, anxiety state, and conjunctivitis. Much medical information can be studied in the official or semi official Reports of Selected War Pension Appeals, from which the above account of the Wills case is largely derived.

Death from Amethocaine

At an inquest in Manchester on Nov 22, a patient was reported to have died from hypersensitivity to amethocaine which had been applied to the throat before iodised oil was introduced into the bronchi.

According to medical evidence, the patient, a 31 year old man, was believed to have bronchiectasis, and the procedure was undertaken for the purpose of radiological examination. 6 ml. of amethocaine solution had been sprayed on the throat, and a further 2 ml placed on a swab, this was probably less than the amount usually employed at the Royal Infirmary where the examination was made. Administration of the amethocaine was completed in a quarter of an hour. Soon

after, without any warning, the patient had two major convulsions, and at the end of the second he died, it was all over in a matter of thirty to forty seconds. Necropsy led to the conclusion that death was due to hypersensitivity to amethocaine. Bronchiectasis was present.

The coroner, returning a verdict of death by misadventure, said there could be no possible criticism of the hospital staff.

Disabilities

54 BLINDNESS FROM RETINAL DETACHMENT

BLINDNESS came to me in two stages. In the summer of 1945, without warning, I lost the sight of one eye. An operation was performed and I lay motionless for ten weeks, but it did no good. On returning to my ordinary business and domestic life I found that my principal handicap was a certain nervousness in traffic. This I overcame in the early days by resisting an inclination to join the District Railway at St James's Park and instead forcing myself to go to Victoria, which involved crossing a busy thoroughfare. I used the homeward bound crowds as unsuspecting guides through traffic. The only other indication of the blindness, which was of the right eye, was constant bruising on that side due to bumping into various objects. Now I realise how fortunate I was to have my full sight for fifty years and half sight for four.

In the autumn of 1949 the retina of the left eye became detached. This detachment came as suddenly as the first, and despite three operations and five months in hospital, I am now quite blind except for a precious bit of light in one corner of the left eye when the sun is very bright. This eye is never "static", always there are varying lights, cloud effects, and flying saucers—in fact almost a private cinema—and this has become part of my life.

Looking back, it seems almost incredible that anyone like myself who has led an active life could lie motionless day and night with eyes bandaged for almost five months in a state of comparative content. I had to learn to distinguish many different voices, and soon found that people are touchy about being mistaken for someone else. This did not worry me unduly, but I imagine that it might upset some patients, and for this reason I think that eye wards should be small—say, six to eight beds—thus reducing the number of people with whom the patient comes into contact. On the other hand, to have been in a room by myself and denied the sounds of ward life would have been intolerable. (Experience convinced me, by the way, that, in an ideal eye ward, bathrooms and lavatories should be very simply equipped, without obstructions of any kind.)

I wonder if doctors and others realise the comfort and confidence it gives when they grip the fingers of a blinded patient by way of leave taking. I received the greatest kindness, but sometimes nurses seemed not to have been told about the special difficulties of newly blind patients. For instance, whereas the surgeon or houseman told me what he was going to do, such as uncovering the eyes or putting in drops, a nurse seldom described the food she was giving or declared when she was leaving the bedside, thus saving me from talking to thin air. This may seem trivial, but it makes a great difference. During these five months although always hoping, I had faced the prospect of blindness, so when I knew I was blind it did not come as such a shock. I was saved what I am told are the common immediate reactions to blindness—first resentment and then despondency.

My great wish was to get home to my flat where I knew every step. Being unable to continue my secretarial

streets, the great buildings set out in carefully tended gardens, Notre Dame, the Louvre the spectacles at the Palais de Chaillot, the excursions to Versailles, to Chantilly, to Fontainebleau, the Sorbonne, so accessible, its theatres so numerous that two international congresses can be held simultaneously and without interference with each other

Paris and French! Why choose French, which is now no longer the language of polish and diplomacy, which is almost unknown to the Anglo Saxon world and is mispronounced so badly by the Italian, Spanish, and South American peoples? How can the nations communicate with each other lacking an international language?

* * *

Our French hosts had prepared the site admirably, had inaugurated the congress with supreme success in the presence of two most important members of the government, had put in presidential and vice presidential chairs men of years and of most honoured names, and then, like the gendarmes on the boulevard, had left the individual to manage for himself his affair

There appeared to be five lanterns, two epidiascopes, and one cinema projector, with two operators between the five sectional theatres. The lanterns appeared to have only one set of slide holders of each dimension, and much time was lost in getting the operator and his slide holders. It appeared too that there was no standard size for lantern slides laid down, or regular means of labelling. Thus many slides would not fit the holder, or were placed sideways or upside down or contained so much data as to be unintelligible and inexplicable. Too often the performance was unrehearsed and the result comic

The quality of the communications varied between the highest standard and fatuity, unfortunately, among a heterogeneous mass of unknowns there can be no seeding and no elimination. National characteristics became evident in delivery. The Frenchman had prepared a complete, rounded, and logical exposition which he delivered at a rapid pace and often in an undertone, intent on getting through his masterpiece in the time allotted. Italians and Spaniards read at speed French translations of their views, nose to paper, with atrocious accent. The Mexicans were good, they came as a team, each had at least one language other than his own, they sat together and were ready then to take up points in the discussion raised in any of the four official languages

Surely there might be an arrangement that eight of the ten minutes should be used to give an outline of the main points of the communication followed by two minutes of summary in French and in English. This summary might be handed to an official interpreter to deliver, then it would not be made unintelligible by indifferent accent. There is much to be said for our insistence that communications must be spoken and not read

At times an interpreter was provided, but he was often non medical and thus unable to give clarity to the points raised. On one important occasion there was no one who could reconcile the issues between an Englishman, a Frenchman, and an Italian. The best mutual interpretation was voluntary, and one whole session was much enhanced in importance and value by an Italian professor who summarised each speaker's words in French and in English

* * *

The value of an international congress lies in bringing workers in the same field of medicine together from all parts of the world, in attempting to standardise methods so that workers throughout the world may use the same notation and mean the same thing and in seeing and hearing men from other countries submitting their views and opinions

Meanwhile, some memories will remain the profoundly significant opening address of the aged president, Professor Laubry, with its insistence that in spite of all the help obtained by instrumental methods these must be subsidiary to examination and care of the patient himself and the clinical aspect, the witty and far sighted allocation of M le Ministre de la Santé Publique at the banquet, the cordial reception and attentive hearing given to Dr Helen Taussig for her communications on the treatment of congenital heart-disease, the admirable collection of portraits of authors and copies of the works of those who had established cardiology, beginning with William Harvey and ending with Thomas Lewis the masterly appeal of Paul D White for world wide research on the cause and management of heart-disease, even the small terminal vignette by the Stockholm professor, Björck, on the social consequences of cardiovascular disease in Sweden, a sound early contribution, all in the unique setting of Paris, Lutetia the lovable, in her infinite variety

A NEW SCIENCE CENTRE

THE Lord President of the Council has announced that we may look forward to having a national science centre in London on a site to be chosen early next year. It will be some years before the Minister of Works can build such a centre, but a start will be made as soon as resources can be found. Within the new centre accommodation will be built for the Royal Society and for other leading scientific societies with their special libraries, most of which are now severely cramped in the rooms provided for them by the Government about 100 years ago in Burlington House or in other inadequate accommodation. The centre will also include the Patent Office and its library (which will be modernised and extended as a reference library on science and technology), the Department of Scientific and Industrial Research, and other Government scientific organisations

Medicine and the Law

Varicose Veins and Military Service

IN deciding how far disabilities are attributable to (or, alternatively, have been aggravated by) war service the series of war pension appeals is assembling medico-legal material of varied interest. The case of Wallbridge v Minister of Pensions, heard on Oct 12 by Mr Justice Ormerod, the "nominated judge" for this purpose in succession to Mr Justice (now Lord Justice) Denning, concerned the disability of varicose veins. The appeal tribunal had decided that the condition was not attributable to, although it was in fact aggravated by, war service. The learned judge dismissed an appeal from this decision.

The appellant enlisted in the R A F in April, 1939, at the age of 50, and at his medical examination was passed as grade 1 with no record of any varicose condition. When his service began in the following September, he was employed in plotting the position of aircraft. In the following March varicose veins were diagnosed with a previous history of varicose conditions in the left leg recurring at intervals. On his discharge in 1945 he applied for a pension, but the tribunal held that the condition existed before his service began. He was awarded a pension on the basis that the condition was aggravated by, but not attributable to, war service.

War pension cases arise on facts which are often too special to make judicial precedents. In the Wallbridge case reference was made to the previous case of Wills v Minister of Pensions, decided a year ago.

Mr Wills suffered from varicose veins shortly after joining the service. As there was a question of predisposition or congenital causes, the case was remitted to a tribunal and the opinion of an independent medical expert (Sir Ernest Rock Carling) was obtained. The latter reported that the plea that wearing heavy boots caused the condition was untenable. Marching he said was not a cause, prolonged standing was undesirable where

there was a varicose tendency, but it was not in itself an efficient cause. If either were in fact a cause of varicose veins, "the ranks of the Army would be riddled with cases." He considered that the varicosity was not attributable to war service, there was inherent weakness of the vein before war service, the varicosity arose during war service but was not aggravated thereby.

The Medical Services Division of the Ministry gave a further opinion, quoting several recognised medical authorities. The consensus of medical authority, stated the opinion, is that varicose veins are related to a congenital and inherited weakness of the walls of the veins and deficiency of their valves. Marching in heavy boots or the wearing of anklets would not produce varicose veins. The Ministry maintained the view that there was "a real preponderance of probability to the exclusion of reasonable doubt" that Mr Wills's disability arose independently of his service and was not aggravated thereby. The appellant's solicitors submitted further medical reports and the independent medical expert expressed a further opinion thereon. He noted the impression that some shop girls develop varicose veins, but there was no statistical evidence that the number was greater among those standing at the counter than among those in the counting house or among men who stand all day at machines. Return of blood through the veins was largely effected by the contraction of the muscles surrounding them, walking or marching, as such, was an advantage rather than a detriment. The superficial veins are not supported by muscles, functional inefficiency between the deep and superficial veins, caused by inherited defect, allows an incommensurate varicosity to develop as a man gets older and the vessel walls become less elastic. The course and the failure of operative treatment in Mr Wills's case made it clear that he suffered from such a valvular deficiency.

The tribunal held that war service did not cause Mr Wills's varicose veins, the injurious process had begun years before, there was a family history, the condition was congenital. The Ministry having discharged the burden of proof on the issue of attributability to war service, the appeal on this point was disallowed. On the issue of aggravation by war service the tribunal could not at first make up its mind, later it gave Mr Wills the benefit of the doubt, being unable to say that military service played no part in causing the deterioration.

On the Wallbridge appeal the judge interpreted the Wills case as establishing that if a man suffered from varicose veins, or if they became manifest during war service, it was difficult for a tribunal to hold them attributable to war service unless there was some evidence of a supervening cause other than the ordinary conditions of war service. In the absence of such supervening cause ordinary service conditions could not be regarded as causing varicose veins although they might aggravate the disability.

The ailments considered in connection with claims for war pension range from Hodgkin's disease, Parkinson's disease, and diabetes mellitus to muscular strain, anxiety state, and conjunctivitis. Much medical information can be studied in the official or semi official Reports of Selected War Pension Appeals, from which the above account of the Wills case is largely derived.

Death from Amethocaine

At an inquest in Manchester on Nov 22, a patient was reported to have died from hypersensitivity to amethocaine which had been applied to the throat before iodised oil was introduced into the bronchi.

According to medical evidence the patient, a 31 year-old man was believed to have bronchiectasis, and the procedure was undertaken for the purpose of radiological examination. 6 ml of amethocaine solution had been sprayed on the throat, and a further 2 ml placed on a swab, this was probably less than the amount usually employed at the Royal Infirmary where the examination was made. Administration of the amethocaine was completed in a quarter of an hour. Soon

after, without any warning, the patient had two major convulsions; and at the end of the second he died, it was all over in a matter of thirty to forty seconds. Necropsy led to the conclusion that death was due to hypersensitivity to amethocaine. Bronchiectasis was present.

The coroner, returning a verdict of death by misadventure, said there could be no possible criticism of the hospital staff.

Disabilities

54 BLINDNESS FROM RETINAL DETACHMENT

BLINDNESS came to me in two stages. In the summer of 1945, without warning, I lost the sight of one eye. An operation was performed and I lay motionless for ten weeks, but it did no good. On returning to my ordinary business and domestic life I found that my principal handicap was a certain nervousness in traffic. Thus I overcame in the early days by resisting an inclination to join the District Railway at St James's Park and instead forcing myself to go to Victoria, which involved crossing a busy thoroughfare. I used the homeward-bound crowds as unsuspecting guides through traffic. The only other indication of the blindness, which was of the right eye, was constant bruising on that side due to bumping into various objects. Now I realise how fortunate I was to have my full sight for fifty years and half sight for four.

In the autumn of 1949 the retina of the left eye became detached. This detachment came as suddenly as the first, and despite three operations and five months in hospital, I am now quite blind except for a precious bit of light in one corner of the left eye when the sun is very bright. This eye is never "static", always there are varying lights, cloud effects, and flying saucers—in fact almost a private cinema—and this has become part of my life.

Looking back, it seems almost incredible that anyone like myself who has led an active life could be motionless day and night with eyes bandaged for almost five months in a state of comparative content. I had to learn to distinguish many different voices, and soon found that people are touchy about being mistaken for someone else. This did not worry me unduly, but I imagine that it might upset some patients, and for this reason I think that eye wards should be small—say, six to eight beds—thus reducing the number of people with whom the patient comes into contact. On the other hand, to have been in a room by myself and denied the sounds of ward life would have been intolerable. (Experience convinced me, by the way, that, in an ideal eye ward, bathrooms and lavatories should be very simply equipped, without obstructions of any kind.)

I wonder if doctors and others realise the comfort and confidence it gives when they grip the fingers of a blinded patient by way of leave taking. I received the greatest kindness, but sometimes nurses seemed not to have been told about the special difficulties of newly blind patients. For instance, whereas the surgeon or houseman told me what he was going to do, such as uncovering the eyes or putting in drops, a nurse seldom described the food she was giving or declared when she was leaving the bedside, thus saving me from talking to thin air. This may seem trivial, but it makes a great difference. During these five months, although always hoping, I had faced the prospect of blindness, so when I knew I was blind it did not come as such a shock. I was saved what I am told are the common immediate reactions to blindness—first resentment and then despondency.

My great wish was to get home to my flat where I knew every step. Being unable to continue my secretarial

streets, the great buildings set out in carefully tended gardens, Notre Dame, the Louvre the spectacles at the Palais de Chaillot, the excursions to Versailles, to Chantilly, to Fontainebleau, the Sorbonne, so accessible, its theatres so numerous that two international congresses can be held simultaneously and without interference with each other

Paris and French! Why choose French, which is now no longer the language of polish and diplomacy, which is almost unknown to the Anglo-Saxon world and is mispronounced so badly by the Italian, Spanish, and South American peoples? How can the nations communicate with each other lacking an international language?

* * *

Our French hosts had prepared the site admirably, had inaugurated the congress with supreme success in the presence of two most important members of the government, had put in presidential and vice presidential chairs men of years and of most honoured names, and then, like the gendarmes on the boulevard, had left the individual to manage for himself his affair

The decoration of the ceilings of the theatres where the sectional meetings were held was of museum status, but the narrow, hard seats with straight backs, the inadequate acoustics, the negligible ventilation, the movement of uncomfortable auditors, the close proximity of the noisy chatter of the assembly court, and the flickle lights. There appeared to be five lanterns, two epidiscopes, and one cinema projector, with two operators between the five sectional theatres. The lanterns appeared to have only one set of slide holders of each dimension, and much time was lost in getting the operator and his slide-holders. It appeared too that there was no standard size for lantern-slides laid down, or regular means of labelling. Thus many slides would not fit the holder, or were placed sideways or upside down or contained so much data as to be unintelligible and inexplicable. Too often the performance was unrehearsed and the result comic

The quality of the communications varied between the highest standard and fatuity, unfortunately, among a heterogeneous mass of unknowns there can be no seeding and no elumination. National characteristics became evident in delivery. The Frenchman had prepared a complete, rounded, and logical exposition which he delivered at a rapid pace and often in an undertone, intent on getting through his masterpiece in the time allotted. Italians and Spaniards read at speed French translations of their views, nose to paper, with atrocious accent. The Mexicans were good, they came as a team, each had at least one language other than his own, they sat together and were ready then to take up points in the discussion raised in any of the four official languages

Surely there might be an arrangement that eight of the ten minutes should be used to give an outline of the main points of the communication followed by two minutes of summary in French and in English. This summary might be handed to an official interpreter to deliver, then it would not be made unintelligible by indifferent accent. There is much to be said for our insistence that communications must be spoken and not read

At times an interpreter was provided, but he was often non medical and thus unable to give clarity to the points raised. On one important occasion there was no one who could reconcile the issues between an Englishman, a Frenchman, and an Italian. The best mutual interpretation was voluntary, and one whole session was much enhanced in importance and value by an Italian professor who summarised each speaker's words in French and in English

54 BLINDNESS FROM RETINAL DETACHMENT

BLINDNESS came to me in two stages. In the summer of 1945 without warning, I lost the sight of one eye. An operation was performed and I lay motionless for ten weeks, but it did no good. On returning to my ordinary business and domestic life I found that my principal handicap was a certain nervousness in traffic. This I overcame in the early days by resisting an inclination to join the District Railway at St James's Park and instead forcing myself to go to Victoria, which involved crossing a busy thoroughfare. I used the homeward bound crowds as unsuspecting guides through traffic. The only other indication of the blindness, which was of the right eye, was constant bruising on that side due to bumping into various objects. Now I realise how fortunate I was to have my full sight for fifty years and half sight for four.

In the autumn of 1949 the retina of the left eye became detached. This detachment came as suddenly as the first, and despite three operations and five months in hospital, I am now quite blind except for a precious bit of light in one corner of the left eye when the sun is very bright. This eye is never "static", always there are varying lights, cloud effects, and flying saucers—in fact almost a private cinema—and this has become part of my life.

Looking back, it seems almost incredible that anyone like myself who has led an active life could be motionless day and night with eyes bandaged for almost five months in a state of comparative content. I had to learn to distinguish many different voices, and soon found that people are touchy about being mistaken for someone else. This did not worry me unduly, but I imagine that it might upset some patients, and for this reason I think that eye wards should be small—say, six to eight beds—thus reducing the number of people with whom the patient comes into contact. On the other hand, to have been in a room by myself and denied the sounds of ward life would have been intolerable. (Experience convinced me, by the way, that, in an ideal eye ward, bathrooms and lavatories should be very simply equipped, without obstructions of any kind.)

I wonder if doctors and others realise the comfort and confidence it gives when they grip the fingers of a blinded patient by way of leave taking. I received the greatest kindness, but sometimes nurses seemed not to have been told about the special difficulties of newly blind patients. For instance, whereas the surgeon or houseman told me what he was going to do, such as uncovering the eyes or putting in drops, a nurse seldom described the food she was giving or declared when she was leaving the bedside, thus saving me from talking to thin air. This may seem trivial, but it makes a great difference. During these five months, although always hoping, I had faced the prospect of blindness, so when I knew I was blind it did not come as such a shock. I was saved what I am told are the common immediate reactions to blindness—first resentment and then despondency.

My great wish was to get home to my flat where I knew every step. Being unable to continue my secretarial

work and having no private income, I had to consider my finances. However, by letting part of the flat to two business girls and with the pension granted I am able to manage. I am glad that my flat faces on to a noisy, traffic-laden thoroughfare in west London—noisy, that is, except between the hours of 10.30 P.M. and 6.30 A.M. Sounds which I previously heard subconsciously have now become a major part of my life and help me to keep in contact with time. In the quiet of the night one can sometimes hear a boat's siren on the river, and that, like the works' whistles at 8 A.M., is a joy to a Clyde born Scotswoman. At about 4.30 A.M. in spring and summer the birds begin to sing, and then it is strange to think one is in the heart of London and that their song will soon be lost in the roar of traffic. At 5.30 the newspapers are delivered to a shop opposite, and by 6 the day's work at that shop has begun.

I have been back at home for ten weeks and can do quite a lot of housework, including baking, washing, ironing, and sewing. Some jobs—for instance, dusting high shelves—have to be done when I am alone, as friends and relations get a bit nervous when they see me attempting what to them seems dangerous. I have been asked how I know when things are cooked. I don't know how I know, but I do. So far my only failure has been when I attempted to make Scotch pancakes. Although I succeeded in getting the mixture on to the griddle, I could not find the pancakes to turn them over, but these pancakes will be conquered yet. I have been twice to the theatre, thoroughly enjoying the plays, and strangely enough I was able to depict fairly accurately the stage settings. Wireless concerts are another joy. All else apart, there is the feeling of being part of the community. I have the same feeling in a restaurant. At first I was reticent about eating in public, but now I do not mind so long as there is someone to cut up the meat. To me it seems essential to make all these efforts—and they are efforts—in the early stages of blindness as otherwise one is apt to become self-conscious.

My great difficulty is in learning Braille. I know all the letters but am slow, and this is the only thing connected with the blindness which irritates me. (I do not even get cross when I lose things. This to me is a great wonderment, for I have always had a wee bit of impatience with any slowness, and I certainly have to go slow nowadays.) However, my Braille teacher assures me that I am making normal progress and that one suddenly finds Braille easy. I am, of course, spoiled by having received from friends a talking book machine. To save my conscience I am learning to make rugs, and while listening I can also knit and sew.

The blind may sometimes seem unappreciative of kindnesses offered and shrink from accepting invitations. Most often this is due to the fear of being a nuisance, especially when one has to be "fetched and returned." Even in the early days I could cope fairly effectively with letter writing by using raised lined paper (which can be purchased from the National Institute for the Blind) for ordinary correspondence, for airmail letters I used this lined paper as a guide, attaching the thin airmail sheets to it by ordinary spring clothes pegs, bulldog or paper clips being less easily manipulated. Now I am usually able to write clear and straight without any guiding lines. In many ways I feel like a child learning something new every day and being bucked with my achievements. A clock that chimes the quarters and a Braille watch are great helps, but I still wear my small, now useless, wrist watch, which I call my "optimism." Each blinded person finds little things which help. For instance, to indicate the top side of my eiderdown I have put a small safety pin in one corner. One should use a glove to replace a saucepan on the hot-plate of the electric cooker. I usually forget and use my bare fingers—which isn't too good for the Braille!

Since I was very young I have always given thanks for the beauties of the world, my home, my family and friends, the work I was able to do, my health and strength, my wholeness of body and mind and my memories. It seems as if that was a sort of premonition, for now that I have lost the wholeness of body, the other "gratitudes" are my greatest comforts. I have been fortunate in having seen quite a bit of my own country and also a few other parts of the world, and these memories of the loveliness of sea and land are now a special joy. (I am glad of the plain, straightforward way we were taught geography when I was young, because I have a very vivid picture of the map of the world.) In my family and friends I am blessed. Since I lost my sight I have received the utmost kindness from all manner of folk met casually, including especially telephone operators and bus conductors. By conductors a blind person is treated as special cargo, and twice lately in a peremptory voice a conductor has called "Which gentleman is giving up his seat," without waiting for the offer which always comes.

That one has an added sense—is it only one?—is undoubtedly true. Even in the few weeks of my blindness I have had the most remarkable experiences, finding with ease something I expected would be difficult to find, changing to a pencil when the pen had run dry—though I had no way of actually knowing it was dry. In fact, so often do strange things happen like this that friends say they think I must see a little. How I wish I could! One of the things partly lost with blindness is privacy, one's life is more exposed. Many people have weaknesses. In my case it is an old maidish habit of turning back when leaving the flat to make sure that the electric power to the cooker is off and this weakness is now sometimes laughed at by my escort. However, the greatest loss of privacy is in the reading of correspondence, one is apt to feel that a third person may find the chat of one's friends a bit stupid. I have (or had) another weakness for reading my letters many times, and I still find it difficult to memorise, from a single reading, all that a letter contains. To ask a person to read a letter more than once is embarrassing—especially if the reader is one of these splendid practical people who read a letter just once and do not hoard correspondence. The remedy for hiding this is to get letters re-read by different folk. Any fear that some people might miss out worrying or controversial parts can be overcome by the choice of readers.

This brings up a very interesting phase of blindness—the reactions of relatives and friends. These are, to me, a source of constant interest. Though everyone is extraordinarily kind the blind one often needs to exercise quite a lot of tolerance as people in their kindness and helpfulness might sometimes irritate but for one's gratitude. I suppose we blind are in many ways more sensitive than when we had our sight. For instance, things people say, often casually, may make a deep impression, and encouragement means a great deal because even when the blinded one is making good progress in rehabilitation and putting a good face on it, his whole life is so changed that a little praise for achievements is helpful. Once I discussed with a young doctor how I would manage if I should become blind, and he assured me that I would never be helpless or a burden, also I was told that I had the courage to face whatever came. Whether or not I merited these opinions, often during the five months I lay in hospital these as well as other encouragements gave me great comfort. At that time I determined that, if I were to be blind, I would try to be one of the "happy blind."

In blindness I have found a deep loneliness, but not a depressing loneliness, because there is a oneness with something outside myself which brings content and acceptance.

In England Now

A Running Commentary by Peripatetic Correspondents

THE last time I had been in the Horticultural Hall was for the Model Engineering Exhibition, a show patronised by old boys and young boys, whereas at the Medical Exhibition there wasn't a boy to be seen. Yet there were a lot of things that would have interested a schoolboy, for even medicine is becoming mechanised, at least in some branches. The show is essentially a trade affair, but it seems a pity that space is not taken by the M.R.C. and other official bodies, after the fashion of Government departments at other technical exhibitions. By this means the balance of the whole would be improved, and general practitioners in particular would see for themselves how far officially sponsored research might influence their everyday work, either in therapeutics or public health. The introduction of official stands might also, by their example in dignified but arresting layout, exert a restraining influence on the means used by some firms to attract attention. In a few cases these were reminiscent of the Great West Road Activity at the stands seemed in fact to be determined almost entirely by the technical excellence of the products on view, no doubt the medical household names always command attention, but their fortunate possessors take jolly good care that their products reach a high standard. I was glad to see that the excellent American method of advertising products with coloured photographs of relevant pathological and other specimens has spread to this country. The programme of medical films covered many aspects of experimental medicine, and it was a pity that the times of showing were not put on the official invitation, because I, for one, went on the wrong day for a film I should like to have seen.

* * *

Not long ago, reading a serious scholarly book about the fifteenth century Florentines, I got what was for me new light on influenza. It seems that the malady visited Florence in fourteen something, and the citizens, like others since their time, found it puzzling. They asked their doctors what it was but the doctors didn't know. So they asked the astrologers. They knew. It was influenza, the influence of the stars. 'Influenza'. The astrologers probably told them which stars. Poor blighters. Groping in the fog of ignorance and superstition, unilluminated by the beams of modern science. "How rich and great the times are now!" We know that there are really *two* influences—A and B.

* * *

Flying saucers¹ have now appeared in my part of England, so they say, and I doubt whether the indigenes who report them are imaginative enough to invent them. Besides, the accounts of round lighted objects flying very fast come from spots miles apart and seem to tally. I wish I had seen them myself, but 11 P.M. is not my usual time for fresh air and exercise. The news has been discussed locally with incredulous uneasiness. The vicar, for instance, smiled uncomfortably and made a witty remark about them. Two able and intelligent men—a headmaster staying here for half term, and an ex-R.A.F. officer—remarked independently that they sounded sinister and perhaps they were Russian, women quoted rumours of 'little men' 3 feet high in a saucer that crashed in America, and one man who had seen them thought they were rockets. But most people passed them off as a vaguely unpleasant joke.

My own guess is that the apparitions are experimental planes, and that the little men were invented by some shrewd official in the U.S.A. who realised that this bizarre touch would bring ridicule on the reports and

prevent the more intelligent public from being too curious. He must be grateful to the romantic journalists who recall the writings of the late Charles Fort and suggest that beings from another planet are keeping a watch on us. Then lately the papers have been recounting the mysterious affair of the ice-blocks found on sheep-pastures, which may or may not be relevant.

Some say that the saucers are meteorites, but would a meteorite follow a coastline? Or would it, when falling headlong check itself and continue on a horizontal course, as one was seen to do here? It sounds much more like a pilot-controlled machine. Anyway, my house hold is now keeping a good look-out, so perhaps my next instalment will be an eye-witness description with diagrams, like the ones we had of the Loch Ness monster!

* * *

"Doctor," cried my Displaced Person, rushing into the bathroom where I was peacefully washing stockings, "two men wish to speak to you!" She was pale and agitated. "Ask them what they want," I said, suspecting that they were selling something. At that she began making the writhing motion of the torso and arms, expressive of distress, which is called wringing the hands. "I can't," she moaned. "They are in uniform." I dried my hands resignedly and accompanied her to the back door, where two stalwarts in smart navy-blue uniform awaited me. They looked imposing but were as mild as lambs. They had come from the water company about a hose which I had reported buying in the summer. It seemed a singularly ill timed visit, considering the amount of water delivered gratis nearly every day for months by Jupiter Pluvius, and I begged them to make my rating assessment as low as possible. The D.P. hovered nervously behind me and displayed the hose. After inspecting the two fat goldfish in my pond the officials went away grinning, and there was silence in the kitchen for some minutes. When I thought the dust had settled I inquired, "Did you think it was the Gestapo?" "I have no need to fear the Gestapo," she replied defensively, forgetting that the Gestapo (Gott sei Dank!) is no more. She has been chased about Europe for ten years ever since she was twenty, and has lost her husband and everything else she possessed, so it was no wonder that, even after nearly a year of security in England, the sight of uniformed strangers on mysterious business had alarmed her. I laughed and explained the workings of our water rate, whereupon she returned to her usual pose of good-natured critical contempt for things English. By the Black Sea, in the good old pre-war days, they ordered these things much better, she thinks. There must be a moral in this story somewhere.

* * *

Iron is not taken with any greater enthusiasm by doctors wives than by ordinary mortals, hence the supply that has remained in our medicine cupboard for further experiments. Jane the original cause of the prescription two years ago, noted that the tablets can be used as a substitute for chocolate beans, but just as her investigations were reaching a critical phase several cases of poisoning by ferrous sulphate tablets were reported in the journals and her work was therefore discontinued. At that time several of our neighbours built themselves rock-gardens with a beautiful brown-grained stone supplied by the local quarry at £8 a lorry-load. Unfortunately, a load of insipid-looking grey surface-rock at £2 was all that we could afford. Then an attempt by Jane to repeat some of her observations led to a controversy with Mummy during which a considerable number of ferrous sulphate tablets were scattered among our heap of grey rocks. After a few showers of rain the tablets disintegrated and a beautiful permanent brown-grained effect was produced by oxidation of the iron now absorbed in the stone. A rockery, cheaper but as nice as anyone else's, has now been made, and, since a search of the literature has revealed no similar cases, our results may be useful to owners of small daughters, tab ferri sulph, or quarries producing insipid-looking grey rocks.

¹ For an enthralling review of the literature extending back to 1702 (even the appellation 'saucer' dates from 1878) and leading to what the publishers justifiably describe as truly astonishing conclusions see Donald Keyhoe's 'The Flying Saucers are Real' London Hutchinson & Co. 1950—Ed. L.

work and having no private income, I had to consider my finances. However, by letting part of the flat to two business girls and with the pension granted I am able to manage. I am glad that my flat faces on to a noisy, traffic laden thoroughfare in west London—noisy, that is, except between the hours of 10.30 P.M. and 6.30 A.M. Sounds which I previously heard subconsciously have now become a major part of my life and help me to keep in contact with time. In the quiet of the night one can sometimes hear a boat's siren on the river, and that, like the works' whistles at 8 A.M., is a joy to a Clyde born Scotswoman. At about 4.30 A.M. in spring and summer the birds begin to sing, and then it is strange to think one is in the heart of London and that their song will soon be lost in the roar of traffic. At 5.30 the newspapers are delivered to a shop opposite, and by 6 the day's work at that shop has begun.

I have been back at home for ten weeks and can do quite a lot of housework, including baking, washing, ironing, and sewing. Some jobs—for instance, dusting high shelves—have to be done when I am alone, as friends and relations get a bit nervous when they see me attempting what to them seems dangerous. I have been asked how I know when things are cooked. I don't know how I know, but I do. So far my only failure has been when I attempted to make Scotch pancakes. Although I succeeded in getting the mixture on to the griddle, I could not find the pancakes to turn them over, but these pancakes will be conquered yet. I have been twice to the theatre, thoroughly enjoying the plays, and strangely enough I was able to depict fairly accurately the stage settings. Wireless concerts are another joy. All else apart, there is the feeling of being part of the community. I have the same feeling in a restaurant. At first I was reticent about eating in public, but now I do not mind so long as there is someone to cut up the meat. To me it seems essential to make all these efforts—and they are efforts—in the early stages of blindness as otherwise one is apt to become self conscious.

My great difficulty is in learning Braille. I know all the letters but am slow, and this is the only thing connected with the blindness which irritates me. (I do not even get cross when I lose things. This to me is a great wonderment, for I have always had a wee bit of impatience with any slowness, and I certainly have to go slow nowadays.) However, my Braille teacher assures me that I am making normal progress and that one suddenly finds Braille easy. I am, of course, spoiled by having received from friends a talking book machine. To save my conscience I am learning to make rugs, and while listening I can also knit and sew.

The blind may sometimes seem unappreciative of kindnesses offered and shrink from accepting invitations. Most often this is due to the fear of being a nuisance, especially when one has to be "fetched and returned." Even in the early days I could cope fairly effectively with letter writing by using raised lined paper (which can be purchased from the National Institute for the Blind) for ordinary correspondence, for airmail letters I used this lined paper as a guide, attaching the thin airmail sheets to it by ordinary spring clothes pegs, bulldog or paper clips being less easily manipulated. Now I am usually able to write clear and straight without any guiding lines. In many ways I feel like a child learning something new every day and being bucked with my achievements. A clock that chimes the quarters and a Braille watch are great helps, but I still wear my small, now useless, wrist watch, which I call my "optimism." Each blinded person finds little things which help. For instance, to indicate the top side of my eideidown I have put a small safety pin in one corner. One should use a glove to replace a saucepan on the hot plate of the electric cooker. I usually forget and use my bare fingers—which isn't too good for the Braille!

Since I was very young I have always given thanks for the beauties of the world, my home, my family and friends, the work I was able to do, my health and strength, my wholeness of body and mind, and my memories. It seems as if that was a sort of premonition, for now that I have lost the wholeness of body, the other "gratitudes" are my greatest comforts. I have been fortunate in having seen quite a bit of my own country and also a few other parts of the world, and these memories of the loveliness of sea and land are now a special joy. (I am glad of the plain, straightforward way we were taught geography when I was young, because I have a very vivid picture of the map of the world.) In my family and friends I am blessed. Since I lost my sight I have received the utmost kindness from all manner of folk met casually, including especially telephone operators and bus conductors. By conductors a blind person is treated as special cargo, and twice lately in a peremptory voice a conductor has called "Which gentleman is giving up his seat," without waiting for the offer which always comes.

That one has an added sense—is it only one?—is undoubtedly true. Even in the few weeks of my blindness I have had the most remarkable experiences, finding with ease something I expected would be difficult to find, changing to a pencil when the pen had run dry—though I had no way of actually knowing it was dry. In fact, so often do strange things happen like this that friends say they think I must see a little. How I wish I could! One of the things partly lost with blindness is privacy, one's life is more exposed. Many people have weaknesses. In my case it is an old maidish habit of turning back when leaving the flat to make sure that the electric power to the cooker is off and this weakness is now sometimes laughed at by my escort. However, the greatest loss of privacy is in the reading of correspondence, one is apt to feel that a third person may find the chat of one's friends a bit stupid. I have (or had) another weakness for reading my letters many times, and I still find it difficult to memorise, from a single reading, all that a letter contains. To ask a person to read a letter more than once is embarrassing—especially if the reader is one of these splendid practical people who read a letter just once and do not hoard correspondence. The remedy for hiding this is to get letters re-read by different folk. Any fear that some people might miss out worrying or controversial parts can be overcome by the choice of readers.

This brings up a very interesting phase of blindness—the reactions of relatives and friends. These are, to me, a source of constant interest. Though everyone is extraordinarily kind the blind one often needs to exercise quite a lot of tolerance as people in their kindness and helpfulness might sometimes irritate but for one's gratitude. I suppose we blind are in many ways more sensitive than when we had our sight. For instance, things people say, often casually, may make a deep impression, and encouragement means a great deal because even when the blinded one is making good progress in rehabilitation and putting a good face on it, his whole life is so changed that a little praise for achievements is helpful. Once I discussed with a young doctor how I would manage if I should become blind, and he assured me that I would never be helpless or a burden, also I was told that I had the courage to face whatever came. Whether or not I merited these opinions, often during the five months I lay in hospital these as well as other encouragements gave me great comfort. At that time I determined that, if I were to be blind, I would try to be one of the "happy blind."

In blindness I have found a deep loneliness, but not a depressing loneliness, because there is a oneness with something outside myself which brings content and acceptance.

In England Now

A Running Commentary by Peripatetic Correspondents

THE last time I had been in the Horticultural Hall was for the Model Engineering Exhibition, a show patronised by old boys and young boys, whereas at the Medical Exhibition there wasn't a boy to be seen. Yet there were a lot of things that would have interested a schoolboy, for even medicine is becoming mechanised, at least in some branches. The show is essentially a trade affair, but it seems a pity that space is not taken by the M.R.C. and other official bodies, after the fashion of Government departments at other technical exhibitions. By this means the balance of the whole would be improved, and general practitioners in particular would see for themselves how far officially sponsored research might influence their everyday work, either in therapeutics or public health. The introduction of official stands might also, by their example in dignified but arresting layout, exert a restraining influence on the means used by some firms to attract attention in a few cases these were reminiscent of the Great West Road Activity at the stands seemed in fact to be determined almost entirely by the technical excellence of the products on view: no doubt the medical household names always command attention, but their fortunate possessors take jolly good care that their products reach a high standard. I was glad to see that the excellent American method of advertising products with coloured photographs of relevant pathological and other specimens has spread to this country. Letters to the Editor

THE PRACTITIONER'S REMUNERATION

SIR,—I have read with great interest your annotation of Nov 18

All must agree that if extra money is to be obtained, the Treasury must be convinced that the claim is sound. Would the Treasury be convinced if it was proved that part of the enormous cost of the health service is due to a system which forces a general practitioner to be a head hunter (capitation) in order to live? A visit to the casualty department of a large hospital or a talk to a consultant after he has finished a session is an eye opener in this respect. Give a practitioner time to do the work for which he was trained, time to take proper histories and fully examine his patients, and a very different picture of hospital practice could soon be painted.

How can this be done? Some have said that the introduction of a graduated capitation fee will solve the general practitioner's problem, that this is not so is indicated by the following table, which was prepared for me by experts

No of patients (total in parentheses)	Capita tion fee	Total (£)	Remarks
1000 (1000)	30s	1500	Will require a basic salary or expenses allowance to meet liabilities
500 (1500)	25s	625	Just about cover expenses
500 (2000)	20s	500	Credit balance of about £300
500 (2500)	15s	375	Credit balance of about £500
500 (3000)	15s	375	Credit balance increased but income tax much heavier
500 (3500)	10s	250	} Big lists need to be discouraged
500 (4000)	10s	250	

After many hours' work it was decided that it was impossible in equity to others to make solvent the men with 1000 patients, except with the addition of basic salary or expenses allowance, without at the same time raising the income of the man with the big list—a step which could never get Treasury approval.

Is it not essential, therefore, that a system be introduced which enables all general practitioners within the service to start their day's work with an untroubled mind, knowing that they are certain month by month to be able to pay their way and meet all practice expenses, no longer haunted by the thought "Have I got enough 'heads' to live?" In order to have a free mind, to be once again a clinician and not a head hunter, there is no other way, taking the long term view, than by means "basically" of an expenses allowance.

This allowance should certainly be enough to allow a practitioner, just starting in practice, to pay his way while collecting to himself patients. The rest of the remuneration structure can then be built round this according to experience, ability, and responsibility accepted.

The General Medical Services Committee base their claim for extra remuneration on the Spens report, but, as you have suggested,¹ surely it would be much safer if the claim was based on the practitioner's deserving to enjoy an income not unfavourable compared with that of his specialist colleagues (which is far from the case at present) and on the recommendation of the Cohen report that this remuneration

should be "commensurate with those in other spheres of medical practice".

Redistribution will certainly take place in time; but time is the essence of the present problem. Statistics show that under the present method of remuneration 1000 doctors would have to be moved from South Eastern England. Can anyone guarantee to rehouse all these doctors in other areas within three years? And all that time bankruptcy draws ever nearer.

The Conference of Local Medical Committees certainly agreed that if any more money was forthcoming, it should be used to increase the capitation fee on the first 1000 patients, yet you admit that this would give an all round increase not confined to doctors with small lists. Do you really think the Treasury would be prepared to provide extra money which would increase the already big incomes of the big list men? Or a court of arbitration?

Finally, at the outset of the new service the profession rejected the idea of any portion of remuneration being universally applicable (unrelated to numbers on list), surely because it was thought to be the first step to a salaried service. How could an expenses allowance for rent, rates, taxes, light, heat, and telephone, be called the first steps to a salary, except in the mind of a Munchausen?

Worthing

HAROLD LEESON

GROSS GASTRIC DELAY SHOWN RADIOLOGICALLY

SIR,—It has long been known that in severe cases of pyloric or duodenal stenosis the residue of a meal may remain in the stomach for days or even weeks. So far as I can ascertain, however, the emptying time in such a case has never been investigated radiologically. Thus the following case may prove of interest.

A man, aged 35, was sent for a barium meal investigation with a history of four years' dyspepsia associated with vomiting every two weeks or so. He was tall and rather emaciated. Screening showed well marked pyloroduodenal stenosis. The stomach was ptosed, atonic, and grossly dilated, and peristalsis was almost absent. A fair amount of "resting juice" was present, and the meal pooled into the bottom of the body or pars media of the stomach giving the typical "semi saucer" appearance of obstruction. An indolent ulcer crater was present on the lesser curvature (a in figure), but this was not tender on palpation. The duodenal cap could not be filled owing to cicatrization from previous healed ulceration. There was nothing in the appearances or history to suggest malignancy.

The surgeon to whom the case was referred decided to operate, but the patient was told he would have to wait for a few weeks before a bed was available. For this reason, and also out of interest, I decided to follow the case through while the patient was waiting.

2 The Training of the General Practitioner London British Medical Association 1950

The stomach was still nearly full after 27 hours, but a little barium had reached the descending colon by that time. Very little left the stomach in the next two days, and the stomach was still more than half full after six days (b in figure), by which time the head of the meal had reached the pelvic colon. After ten days the stomach was a third full and after fifteen days it was still about a quarter full. On the twenty-fifth day there was still an appreciable amount of the original barium meal left in the stomach (c in figure), and on the thirtieth day part of the stomach wall could still be seen outlined with flecks of barium.

The amazing thing about this patient is that he had a good appetite all the time, ate three good meals every day, and worked fairly hard as a printer. Every fortnight or so he vomited a large quantity of food, after which he felt more comfortable and went back to his three big meals a day!

I. EBAN

ADAPTATION IN PHYSIOLOGICAL PROCESSES

SIR,—In discussing the valuable contributions of Professor Selye a distinction must, I think, be made between the facts he presents and the interpretations he offers. I shall deal here with his experiments on exercise, one of the main categories of "stress" which he has studied.¹

The physiological responses to exercise, he finds, are complexly patterned—i.e. they appear as a multifactorial syndrome. Exercising animals to a point of exhaustion led within 48 hours to involution of endocrine glands, the great parenchymatous organs, different parts of the haemopoietic system, and lymph nodes and lymphatic vessels. With the same experimental method Selye produced ovarian atrophy and oestrous disturbances, regression of acinar tissue of the pancreas, a shift of fat from subcutaneous deposits into the liver and various biochemical reactions. Among the other effects of exercise to which he refers are increased excretion of corticoids (previously observed only in race horses), recorded by Venning and Kazmin,² temporary inhibition of urine secretion, a phenomenon originally discovered by Hellebrandt and changes in capillary permeability a subject studied for many years by Eppinger.

All these reactions are non specific and can be elicited not only through exhaustive exercise but also through transection of the spinal cord, starvation, histamine, bacterial toxins, hormones, certain pharmacological substances, anoxia, asphyxia, solar radiation, electrical injury, cold, X irradiation, burns, and trauma.

Selye has proved that basically the animal organism reacts in a constant manner to a variety of "alarming stimuli" of which exercise is one. He clearly differentiates between specific forms of reaction to stress—i.e. reactions which depend upon the nature of the stimulus—and the uniform pattern of the "alarm reaction" and of the "syndrome of adaptation." Thus, it is not justifiable to say that Selye proposes a monistic concept of pathology. In so far as he deals with the synonymy of certain aspects of the physiological reaction to stress, he follows the precedent set by Walter Cannon, whose theories have for many years formed a fruitful basis for experimental research in physiology of exercise.³

A different attitude must, I submit, be taken in respect of the criticism levelled against Selye's views as set out in his chapter on Clinical Applications of the General Adaptation Syndrome Concept. A categorical distinction must be made between adaptations in physiological as against adaptations in pathological processes. This concept, which was first formulated about 1890 by Cohnheim, of Breslau, was admirably presented by his pupil William Henry Welch. "One fails to see in pathological conditions," Welch wrote, "that coordinate and special fitness which we are accustomed to find in physiological adaptations."⁴ Pathological

reactions, he maintained, may or may not be of therapeutic significance, and they may even aggravate the disorder. His thesis was that in pathological processes adaptation is of the kind used in physiological processes for the distinct purpose of bringing about an adjustment of a given function to changed environmental conditions. "We have no reason to suppose," he once remarked, "that the animal body is endowed with properties designed to meet pathological emergencies. Indeed, its sole weapons of defence, often lamentably imperfect for morbid states, are adapted primarily for physiological use." If they do meet certain pathological conditions, the explanation is simply coincidence.

Conversely, there is no evidence that in normal subjects physical exercise can be conducive to any of the clinical conditions which, according to Selye, react in some way or other to A.C.T.H. or 'Cortisone.' Elsewhere⁵ I have dealt with a variety of pathological conditions encountered in athletes, with special reference to apparently healthy persons breaking down during effort. Some of these conditions are specifically produced by exercise, among them being "indisposition after running" or "athlete's sickness" (a syndrome characterised by vomiting, profuse sweating, and headache, commonly observed after quarter-mile sprints), hypoglycemia after marathon races, muscle cramp in gymnasts, or fainting due to gravitatory displacement of blood after exertion. But in a greater number of the pathological states I described, the exercise though often the last contributory cause, did not actually produce them. Examples are coronary occlusion associated with effort, rupture of arteries, paroxysmal anomalies of intracardiac conduction, and haemorrhagic pancreatitis after muscular exhaustion.

All general autonomic adjustments elicited by muscular effort involve endocrine and nervous functions of the kind studied by Selye. This is important since he believes that adaptation energy represents an unspecific pool of physiological driving force that may become exhausted if the organism is exposed to stress, irrespective of its nature.

Exercise may aggravate pre-existing illness. For example, a girl hockey player with myasthenia gravis had to double her daily dose of neostigmine when she resumed training. On the other hand, many diabetics and other chronically ill people do better and need less insulin when they are physically active.⁶ Two of the greatest tennis players in the world today are afflicted with diabetes.

Normal humoral or tissue immunity, however, is not increased through training. Normal immunological reactions are by products of physiological cell metabolism—a concept first expounded by Paul Ehrlich⁷—and contrary to popular belief there is no evidence that a high standard of physical fitness (i.e. a state of adaptation to one of Selye's "stresses") is associated with, or conducive to, heightened resistance towards infectious diseases. Universal protection against infectious diseases is certainly not afforded by physical training. Physical training does not even lead to a general increase of the scope of normal immunological mechanisms.⁸

Selye's material illustrates the correctness of Cohnheim's original thesis by showing that many autonomic adaptations are basically the same whether they are elicited by exercise or—to choose one of Selye's standard experiments—by transection of the spinal cord. His findings corroborate the conclusion that in pathological situations the body is unable to mobilise weapons other than physiological ones. Only in physiological situations do these reactions serve a purpose. They achieve nothing in the way of repairing a severed

spinal cord, nor do they help the organism to resist an attack by the haemolytic streptococcus. The fact that in controlled experiments physiological substances, given in large quantities, may exert a therapeutic influence upon pathological conditions—the recent discovery of the apparent efficacy of ACTH and cortisone on malignant tumours is an impressive example⁶—fits into this concept.

Professor Selye deserves the admiration and thanks of the medical profession for presenting so much new experimental evidence. The most effective answer to his critics he has given himself by stating "Our facts must be correct. Our theories need not be if they help us to discover important new facts."

STREPTOMYCIN AND TUBERCULIN

SIR,—I have already reported in your columns certain observations on the effect of streptomycin on the tuberculin reaction in tuberculous meningitis.⁶ Further experience has shown that in this respect cases fall into three groups as follows:

- 1 Moderate cases, in which the reaction increases at the commencement of streptomycin treatment and then falls away as recovery sets in. When the stage of apparent cure is reached, the test again becomes strongly positive and remains so during convalescence.
- 2 Severe cases, in which the reaction is negative or weakly positive in the early stages and becomes stronger as treatment proceeds. Its subsequent behaviour depends on the course of the disease.
- 3 Very severe cases with a positive reaction in which the outcome is fatal despite treatment. In these cases, the reaction remains positive throughout.

In the light of the above observations, I have now used subcutaneous or intravenous tuberculin in conjunction with streptomycin for some time, varying the dose according to the strength of the reaction.

In three cases I have administered tuberculin intrathecally, but I have now abandoned this route because of the violent reactions which followed.

CASE 1—Aged 10 years. Admitted April 6, 1947. On Oct. 2, 1947, tuberculin 0.01 µg was given intrathecally, in view of the persistence of a high level of protein in the cerebrospinal fluid. The reaction was severe. The temperature rose above 39°C, there was violent headache, and the c.s.f. pressure increased. Two days later 0.1 µg was given, and the same reaction was observed, but subsided within 24 hours. The patient was discharged on Dec. 16, 1947, and has remained well since.

CASE 2—Aged 8. Admitted April 11, 1947. One dose of tuberculin 1 µg was given intrathecally on April 20, 1947, but was not repeated in view of the violence of the reaction. Tuberculin was subsequently given subcutaneously. The patient was discharged on Oct. 5, 1947, and has remained well since.

CASE 3—Aged 6. Admitted Dec. 27, 1947. Owing to the prolonged course of the disease, one intrathecal injection of tuberculin 0.01 µg was given on April 18, 1948. This was followed by a very severe reaction: the temperature rose to over 40°C, the pulse rate to 150, and the c.s.f. pressure so high as to cause exophthalmos. For two weeks symptoms had to be relieved by drawing off c.s.f. After that time it was found that protein had increased from 1.6 to 4 g per 100 ml, and cells (mainly lymphocytes) from 30 to 750 per ml. The patient recovered and was discharged on Sept. 20, 1948.

Though we cannot yet draw any conclusions as to the usefulness of tuberculin in conjunction with streptomycin, it is the general opinion in our clinic that tolerance to tuberculin increases during streptomycin treatment.

BACTERIAL SYNTHESIS OF VITAMIN B₁₂

SIR,—I have read with great interest the article by Dr. Dyke and his colleagues, in your issue of March 18, and I should like to add some comments.

In a bacteriological investigation of the mucosa of fresh pig stomach and of three commercial preparations from different factories of pig stomach against pernicious anaemia, I have constantly found considerable numbers of only two types of bacteria—*Bacillus subtilis* and one of the non-pathogenic corynebacteria. I therefore presume that one of these bacteria may be identical with the "intrinsic factor".¹ Later investigations have shown that both these bacteria synthesise vitamin B₁₂ in amounts that may be supposed to be important for the concentration of B₁₂ in intestinal mucosa.

Clinical investigations with strains of these bacteria in cases of pernicious anaemia have hitherto not given convincing results, but the provisional results indicate that these bacteria, besides producing vitamin B₁₂, by their synthesis of antibiotics, are able to control unwanted bacterial growth in the intestinal mucosa in these cases.

This has led to the following working hypothesis of the aetiology of pernicious anaemia: if vitamin B₁₂ is to be absorbed it must be present in intestinal mucosa in a concentration higher than that in the tissues. This is the case in the normal organism, where the intestinal mucosa is infected with B₁₂-producing strains. In the diseased organism these strains are expelled from the mucosa and replaced by B₁₂-consuming *Bact. coli* and lactobacilli, and thus mucosa forms a barrier to the absorption of B₁₂ from the intestinal contents.

Further investigations are being made on the basis of this working hypothesis.

HOSPITAL ADMINISTRATION

SIR,—It would be difficult to overrate the importance of your correspondent's article of Sept. 30 under the title Preface to Hospital Administration. It is stimulating chiefly because it insists that hospital administration is one thing, and that the services and crafts which go to meet a hospital's physical problems are another. These functions are all too frequently confused, and the confusion has increased because there has been limited experience in procedures for meeting the growing needs of the Ministry of Health for standardised practices and tabulated information.

Dr. MacWilliam's thoughtful letter (Nov. 11) is an evidence that in the present transition in the health services this distinction is likely to be smothered in a welter of administrative conveniences and methods. Reverts of the principles set out by Dr. MacWilliam are likely to accept them without, perhaps, realising their far-reaching implications. The questions posed by him focus our attention on some of the difficulties and dangers of the present attempt to weld together two different conceptions of hospital practice and control. But the distinctions between the voluntary hospital and local authority hospital lay not in accountancy techniques, budgetary controls, and other tools of administration. The distinction was rather in responsibility. On the one hand this responsibility was carried entirely by the hospital board and its administration, and was immediately affected by public reactions to its policies. On the other hand there was an administration responsible in an auditing sense to a financial authority outside the hospital, elected for other than hospital tasks, and having no special sanction or experience in the field of economy consistent with the requirements of the sick. Dr. MacWilliam's analysis demonstrates some important

aspects of the hospital problem, but does not, I am afraid, lessen the confusion between administration and administrative machinery.

The Preface to Hospital Administration, rightly in my opinion, forces us back to the single minded approach of Florence Nightingale. The changes in medicine and in the scope of hospitals in the last hundred years do not affect the fundamental purpose of hospital administration, described in her words "Administration is intended to enforce economy as far as it is consistent with the requirements of the sick." The plea of the writer of the Preface is that we must give more enlightened attention to that enforced economy. His whole thesis is the inherent unity of administration. There are not medical, financial, clerical, and other administrations, as suggested by Dr MacWilliam. In fact it is the administrator, correctly advised, who must ensure that all aspects of the requirements of the sick shall be in competent hands. It is not his duty to see that nurses nurse or cooks cook, but rather to equate the needs of each with the power and income of the hospital.

In his Chadwick lecture, annotated in your issue of Nov 11, Dr Goodman outlined the system of public health administration on the Continent, and called attention to the different ways in which administration is viewed abroad and in Britain—a science as against 'an art (or even a craft)'. In that difference lies the answer as to the kind of person and his disciplines required for successful administration. How inadequate would be our understanding of Florence Nightingale if we attempted to account for her immeasurable contribution to hospital management solely from her nursing vocation! For we would overlook her "grown up man's attitude" of reflection upon principles, her clarity of mind and purpose, her selfless leadership, and, fundamentally, her courage.

Successful administration does not, as Dr MacWilliam seems to suggest, need to admit the limitation of doctors, accountants, and so forth, for there are no limitations to their contributions as specialists and technicians in their own fields. The task of administration is not simply to add up the answers given to medical questions by doctors, and to financial questions by accountants, but to inspire the combination of those answers which will ensure the "enlightened pursuit of economy."

The safeguarding of the interests of the consumer would appear, according to Dr MacWilliam, to be a task for the administrator, whereas we need go no further than the words of Florence Nightingale "Publicity and the collision resulting from publicity are the best guardians of the interests of the sick." If reflection and experience are needed for (in Collingwood's words) "a grown up man's attitude" to the complexities described in the Preface to Hospital Administration and the observations of Dr MacWilliam, then the 'grown up man' who shall be able as administrator to pursue with enlightenment the "enforced economy" will not be found more in one class amongst the many professions that go to make up the complete hospital or health service than in another. This is amply demonstrated by many names which come to mind. He will be found equally commonly (or rarely) among doctors, accountants, economists, lawyers, and so forth. It is from administrative competence and experience that he must achieve balance and proportion in the many competing needs of the hospital—or rather of the patient. In addition, hospital administration must relate the requirements of the sick to local authorities' responsibilities in preventive medicine and the general practitioner's impact on the life of the potential patient.

To comprehend the interrelations of the specialties, the tasks of the doctors, the work of the matron, the meaning of the financial statement, the responsibilities of the committee, is the administrator's job—a job

quite distinct from the practice of the sciences, arts, and crafts performed by these specialists. He will understand their needs, because his experience must include a close study of every activity in the hospital. To none can the hospital's administration delegate execution and responsibility in the enforced pursuit of an economy which shall be consistent with the requirements of the sick. As the administrator must practise enlightened economy—let us return to the original meaning of the word—he must manage the house in such a way as to ensure that these requirements shall be met.

TUBERCULIN AND STREPTOMYCIN IN TUBERCULOUS MENINGITIS

SIR,—The article of Aug 19 by Dr Smith and Dr Vollum may well herald an important advance in the treatment of tuberculosis. For this reason, some work that I have attempted at Black Notley Hospital may be of interest, though no claims are made for it.

In 1942, having for many years tried various types of tuberculin with no success I began to try, on theoretical grounds, a very carefully filtered and bacteriologically tested filtrate of tuberculous pus from cold abscesses, given subcutaneously. I had seen, as I thought, some general as well as local benefit after operations on tuberculous bone in patients with multiple tuberculous lesions, and believed that this might have been due in part to a specific auto inoculative effect. I hoped that the filtrate might produce a similar effect.

It has been used most often for patients with severe disease not responding to ordinary methods of treatment, I have never seen any harm due to its use and have suspected that benefit has followed on some occasions. No local or general reactions have been seen except rarely a mild protein reaction, and in one patient a possible allergic reaction without constitutional disturbance. I have used it to augment streptomycin treatment in a small series of patients suffering from tuberculous meningitis whom I have treated here. The recovery rate of these patients has been higher than the accepted normal recovery rate, on the other hand, good results have also been obtained in patients treated with streptomycin only.

The following are brief accounts of these cases.

CASE 1—Aged 10 years. Admitted on Dec 20, 1948 with established tuberculous meningitis. Tubercle bacilli present in cerebrospinal fluid (C.S.F.) (culture and guinea-pig). Intrathecal and intramuscular streptomycin given and also during the first month of treatment nine injections of filtrate 0.5 ml. diluted with equal amount of sterile saline. Recovered and discharged on Sept 27 1949. Well since.

CASE 2—Aged 7 years. Admitted on Oct 9, 1948 with established meningitis. Tubercle bacilli present in C.S.F. (culture and guinea-pig). Treated with intramuscular and intrathecal streptomycin. During first month of treatment had also nine injections of filtrate 0.5 ml. diluted with equal amount of sterile saline. Recovered and discharged on Sept 23 1949. Well since.

CASE 3—Aged 43 years. Decompression operation for tuberculous spondylitis with paraplegia on June 17 1949. Streptomycin umbrella before and after operation for twenty six days. Onset of tuberculous meningitis six weeks after operation. Tubercle bacilli present in C.S.F. (guinea-pig positive). Treated with intrathecal and intramuscular streptomycin. During first three months of treatment she also had thirty six injections of filtrate, 0.75 ml. in an equal amount of sterile saline. Discharged well on May 23, 1950. Has remained well. Also recovered from paraplegia.

CASE 4—Aged 4 years. Admitted on Dec 1 1949 suffering from tuberculous meningitis. Tubercle bacilli present in C.S.F. (guinea-pig positive). Treated with intrathecal and intramuscular streptomycin. During first two months of treatment he also received nineteen injections of filtrate, 0.5 ml. diluted with equal part of sterile saline. Patient has

been ambulant for four months. Apparently full recovery except that cells in c.s.f. are still 20 per c.mm.

CASE 5—Aged 15 years. Admitted with very active tuberculosis of the uterus for which biopsy was performed under a streptomycin "umbrella" on June 26, 1950. The biopsy findings were positive for tuberculosis. Onset of tuberculous meningitis on July 3. Streptomycin given daily in doses of 100 mg intrathecally and 1 g intramuscularly. Spinal block threatened and streptomycin level in c.s.f. rose to 32 µg per ml. Dose of intrathecal streptomycin was decreased and of filtrate injections was increased to daily injections until some local allergic reaction seemed to appear, when these injections were stopped. The dose of filtrate was 1 ml diluted with equal amount of sterile saline. c.s.f. became clear, and patient's condition improved until there are now no abnormal symptoms or signs except in the c.s.f. Tubercle bacilli have not yet been found in the c.s.f.

CASE 6—Aged 14 months. Onset of tuberculous meningitis on Oct. 20, 1948. Intrathecal and intramuscular streptomycin started. Child's condition deteriorated, bilateral papilloedema and blindness developed, and there were extensive pareses. Four doses of filtrate given in November but supply ran out. Filtrate recommenced on Dec. 23. Eleven injections given, each of 0.35 ml diluted with equal amount of saline. Improvement noted. Cell count in c.s.f. progressively diminished, but signs of gross changes in the central nervous system persisted. Died of intercurrent bronchitis on Jan. 23, 1949. At post-mortem examination diagnosis of tuberculous meningitis confirmed, amount of exudate in interpeduncular space not conspicuous.

In the next three cases tuberculous meningitis developed after injections of filtrate had been given in the course of treatment for tuberculosis elsewhere.

CASE 7—Aged 24 years. During course of treatment for tuberculous hip had nineteen injections of filtrate. Later had osteotomy of hip, which was followed by tuberculous meningitis. Transferred to special centre where she recovered. Tubercle bacilli never found in c.s.f., but were present in pus from hip.

CASE 8—Aged 12 years. Treated between 1945 and 1948 for tuberculous hip, during 1946 course of filtrate injections was given. In 1948 developed tuberculous meningitis. Tubercle bacilli found in c.s.f. Transferred to special centre. Recovered.

CASE 9—Aged 10 years. Had been treated from 1942 to 1946 for tuberculous spondylitis. In 1942 had had five minimal injections of filtrate. Readmitted in 1948 with tuberculous meningitis. Transferred to a special centre where he died. Diagnosis confirmed at post-mortem examination.

Lastly, there are four cases in which no filtrate was given at any time, and one of a patient who had recovered from tuberculous meningitis but who was given some filtrate injections later in the course of treatment for multiple lesions.

CASE 10—Aged 15 years. Tubercle bacilli found in c.s.f. Full recovery on streptomycin treatment.

CASE 11—Admitted with multiple tuberculous lesions, unilateral ptosis, and increased number of cells in c.s.f. Tubercle bacilli not found in c.s.f. With streptomycin therapy recovered from presumed tuberculous meningitis. Tubercle bacilli present in sputum. Given some filtrate injections later for multiple lesions.

CASE 12—Aged 11 months. Admitted with presumed tuberculous meningitis and tuberculosis of the knee. Tubercle bacilli not found in c.s.f. Treated with streptomycin. Died, no post-mortem examination.

CASE 13—Aged 10 years. Admitted in 1947 with tuberculous arthritis of knee. Developed meningitis. Transferred to a special centre. Recovered.

CASE 14—Aged 4 years. Treated for lupus of face. Developed tuberculous meningitis (1947) and transferred to special centre. Recovered.

Six patients, therefore, had treatment with streptomycin and filtrate. Of these, three have recovered, one has almost fully recovered, one with presumed tuberculous meningitis is recovering, and one infant who received filtrate late in her illness died. Of three patients who received filtrate injections in the course of treatment for tuberculosis but who later developed meningitis two recovered, the third, a child who died, had six years

previously received only a few minimal injections. On the other hand, of five patients who had no filtrate treatment four recovered.

No claim is made for the efficacy of this filtrate. At present laboratory investigations are being considered, and if evidence is found that it has therapeutic value, a further report will follow.

Black Notley Hospital
Braintree, Essex.

M C WILKINSON

TROPHIC AND TROPIC

SIR,—I observe that it is becoming current practice to speak of the action of a hormone in controlling an endocrine gland as *trophic* (e.g., *thyrotrophic* hormone and *gonadotrophins*), and that this usage is common not only in America but also in this country.

This is surely a misuse of words, from a confusion between trophic action (*τροφή* nourishment) which is concerned with nutrition, as in "trophic nerves," and tropism (*τρόπος* a turn, in biology, the movement in a particular direction in response to some stimulus), which connotes control. The pituitary does not nourish the thyroid or the ovary though it does control their activity. Is it too late to revert to *thyrotropic* and *gonadotropic*, and the like?

Department of Pathology J HENRY DIBLE
Postgraduate Medical School of London W 12

VEGETATIVE REGULATION OF THE CENTRAL NERVOUS SYSTEM

SIR,—It is known that single organs (e.g., heart, lungs, liver, and kidneys) function under the control of the vegetative nervous system, the regulation being exercised directly by nervous influences (sympathetic and parasympathetic) or indirectly (humoral), though the proportion of each component may vary. When several organs are connected together in a system, functional adaptation is necessary to meet the needs of the whole organism, and this adaptation too is accomplished under the influence of the vegetative nervous system.

Up till now, the vegetative nervous system has been accepted as affecting only the viscera, the blood vessels, the sweat glands, and other non nervous organs not subject to voluntary control, while its significance for the central nervous system itself has not received any attention. Rein¹ has written of the autonomic nervous system "Today one may accept as definite that there is hardly any part of any tissue which is not vegetatively innervated." This statement is applicable not only to organs supplied by peripheral vegetative nerves, but also to the central nervous system itself, especially the cortex. Hess has shown that stimulation of vegetative centres of the diencephalon produces effects which we accept as vegetative phenomena (e.g., increase in the heart and respiration rates) and we can therefore accept, on the same level, the observation of Murphy and Gellhorn² that when the hypothalamus is stimulated the productivity of certain areas of the cortex is altered, and that changes in the functioning of these same areas take place, only with simultaneous sympathetic effects at the periphery.

These and other findings lead one to conclude that the cortex is subject to vegetative regulation, that this "central nervous vegetativum" is connected with the vegetative centres of the diencephalon, and that by these means all the organ systems including the central nervous system (cortex) are co-ordinated. The idea is further supported by the finding of myself and Will³ that electro shock primarily affects the diencephalon, and that the reaction level (*Reaktionslage*) of the cortex (e.g., that of the area striata examined in the formation of the action potentials caused by rhythmically flashing

¹ Rein H. Einführung in die Physiologie des Menschen. Berlin 1941.

E. SCHUCHARDT

REVOLT AT KINGSTON

SIR,—Unfortunately Dr Stark Murray's letter last week shows little sign of his having benefited from any of the wisdom of your leading article of Nov 11

Rarely, if ever, do "revolts" arise from purely unilateral causes, and surely this "revolt," if not based on any unwisdom in the decision, must imply some inadequacy in the regional hospital board's efforts to enlist the coöperation of all the persons likely to be affected. To take two examples from Dr Stark Murray's letter: the assistance of the press can surely be secured more effectively than by handing its representatives six foolscap pages, and surely the board can exert more effective medical leadership than to announce such a decision when "the staff at Kingston Victoria have never held a meeting to discuss this question"

We all hope that this and other regional boards will always remember their responsibilities, not only for correct decisions, but also for leadership, more especially when the led show signs of being refractory

RUSSELL FRASER

INTEGRATIVE SOCIAL RESEARCH

SIR,—The effort to follow up the constructive social work of Wilfred Trotter continues at Braziers Park, and a second discussion and conference will be held there during the weekend Dec 8-10

It may be of interest to a larger circle of your readers than those who can attend such a conference to mention that a little inquiry into the treatment of Trotter's work by professional sociologists has revealed a rather curious fact: there seems to be no disposition on their part to take seriously the implications of Trotter's conception of a unitary organism based upon a number of human minds considered in conjunction with the tendency of maturing minds to differentiate either towards a resistive or towards a 'mentally unstable' type, with the notable exception of Sigmund Freud

I shall be very glad to send an invitation to this conference to anyone interested

STUDY OF DELINQUENCY

SIR,—While Dr Stott is to be congratulated on his provocative study of delinquency, and particularly on his insistence on observation and avoidance of "blanket" terms, I do deplore the unfair and one-sided picture of clinical psychiatry that is proffered

A bias against doctors appears to raise its head, almost worthy of the late G. B. Shaw. Is it really true that the 'psychiatric examination at the best discovers nothing that the most ordinary inquiry into the behaviour of the patient would not reveal'? In my own experience I have found the various projection techniques very valuable substitutes for actual behaviour studies. I am astonished that Dr Stott imagines that the standard treatment interview for the adolescent delinquent is an hour on the analytic couch. Such a phantasy would be comic if it were not so grotesque. Dr Stott's experience of the psychiatric treatment of delinquents appears strangely limited

In my practice which includes boys and girls from hostels for maladjusted children and from approved schools I spend a very considerable proportion of the session in consultations with the wardens, matrons, housemasters, and headmasters, and discuss the family

situations not only with the patients themselves, but also with the probation officers and other welfare officers who have visited the homes, as far as my knowledge goes this is current practice amongst the colleagues who are doing similar work

Dr Stott speaks of the "inadequacies of our old-fashioned brethren" whose ideas and methods have been borrowed from physical medicine, but a few paragraphs back he had been denouncing their mystic beliefs about the value of analysis, or the reality of character traits. Materialists or mystics? Can he have it both ways? I note that Dr Stott is not without his own beliefs and disbeliefs: he apparently does not believe in projection techniques but does believe in habits. Incidentally when does a habit become irreversible? And what is the difference between an irreversible habit and a character trait? Or is an irreversible habit merely a "dominant pattern of reaction"?

While warmly commending Dr Stott's clinical observations, I must correct the biased picture of psychiatric practice presented in his paper. Dr Stott's experience, some of it obviously based on hearsay evidence, has been unfortunate, and it is to be hoped that a wider experience will lead him to modify the generalisations based on a few particular instances, and that he will regain mastery of his "statistical steed"

Bristol

FRANK BODMAN

CHLORAMPHENICOL IN TYPHOID FEVER

SIR,—Last week's case report by Dr Colquhoun and Dr Weetch undoubtedly presents interesting features. It would be more interesting still if they would explain how and why a case of typhoid fever came to be treated for a period of two months in a large general hospital rather than in a hospital for infectious diseases where the staff are specially trained in the precautions necessary to avoid further spread of the infection

Gateshead
Medical Officer of Health

JAMES GRANT

"SITTING IN" ON PRACTICES

SIR,—In his report on the state of general practice, Collings¹ described his method of "sitting in" with a general practitioner at work. Collings was concerned to assess standards of practice, but it occurred to us that the same technique could be used as a means of postgraduate education, and for sharing knowledge between practitioners

Of the new illnesses seen by the practitioner in his daily work, 85-90% are treated by him from beginning to end. On entering practice doctors have only general ideas about handling such illnesses, which are not regularly seen during their hospital training, but in time the doctor invents for himself methods of handling patients short-cuts to diagnosis, and techniques of treatment. These personal advances do not ordinarily enter into the general body of medical knowledge and, with the practitioner isolated as he now is, they die with him

One of us therefore 'sat in' on the practice of the other for a week attending surgeries, accompanying him on visits, questioning patients, making examinations, discussing diagnosis and treatment, and comparing methods of organising work. We found this greatly to our mutual advantage, and propose a return visit next year

In the correspondence following the Collings report it was suggested that patients might resent the presence of a second doctor. This was not found to be so. After a friendly word of introduction, no patient seemed in any way inhibited by the presence of a professional colleague

While the general practitioner can, by reading, keep himself reasonably *au fait* with recent work in the specialties, he can learn of advances in general practice only by contact with his fellow practitioners, and we feel that this method of postgraduate instruction merits a wider trial. The postgraduate dean of a university medical school might maintain a list of general practitioners willing to teach as they worked, and by introducing countryman to townsman, and Englishman to Scot, he might spread the personal advances of the few among the practices of the many. Recognition of this type of refresher course should be followed by the granting of subsistence allowance and remuneration of a locum tenens, which can already be claimed by those attending such courses in hospitals.

Finally, the system might be extended to the hospital worker, junior or senior. From the general practitioner the specialist might gain a new perspective, while the family doctor would learn, through his own cases, of the latest advances in the visitor's specialty.

N B EASTWOOD
R J F H PINSENT

REGISTRARS

SIR,—Your recent editorials do less than justice to the cause of the registrars. You appear to have lost sight of the fact that circular RHB (50) 106 makes a drastic cut in the numbers of doctors who are today giving good and mostly whole time service to the hospitals. It is not particularly the arbitrary nature but the extent of the proposed cut which is the cause of anxiety. You ignore the immediate issue—that this cut will drastically reduce the scope and quality of the already existing hospital and specialist services—as well as the fact that expansion in the future will be made more difficult.

The registrars are quite prepared to consider that there should be a proper review of the whole position. They are not likely to regard the Ministry's circular as a proper review, or to agree that adequate consultations have taken place with those responsible for the hospital services or those representing general medical services. Both these complementary aspects of the National Health Service would be considerably altered if the circular were carried into effect.

It is difficult to follow your arguments about "economic facts" (Nov 25). This circular simply proposes to cut the number of registrars by "upwards" of 1100. These registrars will be compelled to seek some other employment. Most will rightly wish to do so in their own country. No saving can be effected by transferring the pay accounts of these doctors to a different column in the National Health Service ledger. Moreover, it is difficult to persuade registrars of the economic necessity for this step when it follows within a few weeks the secret distribution of merit awards against which many distinguished voices in the profession were raised and whose total amount would go far to establish fresh consultant posts.

It is pointless to relate future registrar posts to the number of consultant posts likely to be available when the number of such posts is already inadequate for the work done¹ and much of it is therefore necessarily carried out by existing registrars. Visiting committees are already attempting to assess this need, and no reason is given for the necessity of taking this precipitate action in advance of their report. The proper preliminary steps would be to establish the number of consultant posts necessary to give an adequate service to the public even on the present standard of service, create the new posts involved, fill them from the ranks of the trained regis-

trars, and then consider what must be done to bring the number remaining into line with future possibilities.

The alternative measure proposed for staffing hospitals in place of the 800 senior registrars, most of whom are engaged full time, is the employment of part time general practitioners. It is quite clear that the necessary numbers do not exist today, nor are they likely to live in the places where they are needed. Indeed, it is disturbing that it can be suggested that there are doctors with the higher qualifications and necessary experience who are not doing more than part time work today in general practice.

In the appendix attached to this circular no mention is made of the fact that the clinical assistantships might be available to displaced registrars. Indeed, the only suggestions made are that the sacked registrars can either join the Army or leave their country. Moreover, the appendix gives examples of vacancies which exist today and which have existed for some time and which no present registrar has been tempted to apply for because the terms and conditions of service are not sufficiently attractive. The position was neatly summed up by the chairman of the Medical Priorities Committee Lord Haden Guest: "The usual objections made to Service life, besides unfavourable pay, were that it cut a man off from his profession, limited his medical experience, and took him abroad. Then when he was between 50 and 60 it left him stranded with a smallish pension and nowhere to go. Much the same objection applied to the Colonial Medical Services." Registrars would agree that the proper way to fill these jobs is to raise their standard and not to force doctors to accept them as an alternative to unemployment.

Dr Talbot Rogers's thoughtful contribution to your last issue is to be welcomed as suggesting a partial solution to one side of this problem. A number of registrars have always chosen the alternative of general practice of their own free will, and a considerable number have always known that they have this alternative before them if they find their attempts to specialise either uncongenial or unrewarding. What is new in this circular is that many registrars will be forced to take this course against their will. A number, too, who have every reason to believe that they would make good consultants from their experience of the work, are now to find themselves dismissed either for geographical reasons or because they have finished the prescribed course of training and no further vacancy exists to enable them to continue to give their best service.

It is probably correct to argue that the difficulties of entering into general practice hindered a number of registrars, particularly those in their earlier years, from making this choice. Nor can such reports as that of Dr Collings² encourage these keen young men. However, Dr Talbot Rogers thinks that the main stumbling blocks to entering general practice are lack of suitable premises and methods of payment. These two difficulties must be overcome, but it is hard to agree that his solutions are revolutionary; they are simply novel. A much more revolutionary and none the less more acceptable solution would be to start the building of health centres where they are most needed and offer the choice of a salary as an alternative to capitation fees to those willing to work in them. It is not likely that a patchwork attempt to get other bodies such as RHBs to ease their consciences by contributing to the financial support of their displaced erstwhile servants will be satisfactory.

One other major weakness of Dr Talbot Rogers's approach is that if RHBs in consultation with local medical committees—i.e. the representatives of those already in practice—and that there is a suitable general practitioner already established, he is to get the available

¹ National Health Service The Development of Consultant Services Ministry of Health H M Stationery Office 1950

clinical assistant post without advertisement to others. No doubt Dr Talbot Rogers did not mean this but that is what his article implies. Furthermore, the local medical committee, financially interested in what the newcomer takes out of the "pool," is to be the judge of the limits to be placed on the newcomer's general practice. Registrars are to be neither fully fledged specialists nor fully fledged general practitioners. The only way in which such a person could be happily and usefully employed would be as part of a team of doctors working together at a health centre, not competing one against another but enjoying an agreed salary and performing a mutually agreed amount of work. The most important contribution of the article is the realisation that the urgent need exists today for a revolutionary change in the whole attitude towards co-operation between hospital and specialist services on the one hand and the general medical services on the other. Combined machinery to deal with the whole problem should be set up on a more authoritative and permanent basis than that of liaison. Changes are necessary, and, even though they clearly cannot be carried out on the lines of the Minister's circular they will affect specialists and general practitioners alike. It is time that the profession learnt to work in concert to determine its own future.

Whatever the ultimate solution it is clear that circular R.H.B. (50) 106 is unworkable and all organisations concerned with the present and future medical services of this country should lose no time in urging the Ministry to suspend the action of this circular until further consultations take place. The position is critical, for many appointments will shortly terminate and no openings at all will be available if this uncertainty continues. New specialist staff must be appointed, at least adequate to continue the work which the hospitals do today, and the machinery for combined action of local medical committees, executive councils, and the R.M.B.S. and boards of governors should be set up. If these measures are taken first, the profession acting together is capable of solving the problem which is before it in such a way that those registrars who do not secure the further posts to be created can yet be assured of a useful place in the medical services of this country in which their skills can be adequately used. I would finally plead that the registrars themselves be invited to make their contribution to the solution of a problem in which they are so particularly involved.

London W

I C GILLILAND

SIR,—It has been suggested that the Ministry of Health circular on registrars was issued at the behest of the Treasury. Whether or not this is true, it seems reasonable to ask if the Minister availed himself of any expert professional advice before recommending this course. If he was guided by expert advice, then the threatened registrars are entitled to know who his advisers were and how they justify these recommendations. If, on the contrary, the Minister adopted this panic measure solely at the crack of the Treasury whip then one must surely doubt whether he has the true interests of the service at heart. Anyone familiar with the work done by the majority of registrars would realise that the proposed drastic cut in their numbers can only lead to serious curtailment of the hospital service.

At the present time there is some confusion because the registrar body subserves two functions. Firstly there is a large number of senior men (some of whom are long qualified and very experienced) who are apprenticed to established specialists of some repute and, secondly, there are others who are subserving the function of R.M.O.s and R.S.O.s in district hospitals. In addition, in some district hospitals there are general practitioners who for the purposes of salary are graded as registrars. It would seem that the first group, consisting chiefly

of senior registrars (who are truly trainee specialists), should bear some numerical relation to future consultant vacancies but it is arguable what this relationship should be. The second group are doing important hospital work in assisting consultants, and helping in the training of junior resident staff, some of these men may subsequently pass on to trainee consultant appointments but the remainder will go into general practice and other fields of medicine. These two groups are at present included in the generic term "registrar," and the future efficiency of the health service depends upon the wise and just management of both groups. Some of our present difficulties stem from the fact that a proportion of men holding ostensibly training posts are being treated as a valuable source of hospital labour. While not denying that this work gives these men some useful experience it is questionable how far hospitals which use their registrars in this fashion can provide adequate consultant supervision and apprenticeship. Some hospitals with senior registrars have neither suitable facilities nor good enough consultant staff to give a thorough specialist training, and yet such hospitals would often afford valuable experience to senior registrars already trained elsewhere. The benefit in these cases would be by no means one sided for such men would do much to improve the standards of the less efficient or smaller hospitals to which they were seconded in the later stages of their training.

While there is perhaps, a case for some limitation in the number of higher-grade trainee consultants in the way I have suggested, there seems no possible justification for making the over-all reduction proposed by the Ministry. The removal of large numbers of registrars will, in most cases, deprive the hospitals of help which they will have to obtain in some other form if they are not to lower the standards of their service. At least one of the regional hospital boards has recently held a meeting of consultants at which the majority of those present expressed the view that a literal interpretation of the Ministry of Health instruction would lead to a reduction of up to 40% of the services available in the various departments of the hospitals in that region.

The dangers inherent in the Ministry of Health undertaking responsibility for medical educational matters of which it has no knowledge or experience were mentioned by Sir Francis Fraser¹ more than four years ago. It seems intolerable that any Minister should wield such powers in respect of medical education. While the Minister is ultimately responsible for the health service, the proper training and provision of specialists is a matter for the expert attention of the profession alone. Surely this is an important field of activity for the Royal Colleges, and yet they have sometimes seemed strangely mute in recent years.

Does not the proper solution of this problem lie in making some purely professional body responsible for all matters connected with postgraduate training? Only thus can we protect our specialist services from the whims of the Minister and the dictates of the Treasury. The future high standards of consultant work and much of the freedom of medical research, are jeopardised by the present powers of the Minister and it is plainly essential to protect them both from all forms of political interference and patronage.

Radlett Herts

REGINALD S. MURLEY

SIR—The Gordian knot of excess registrars is being cut in high style. In any scheme whereby progress depends on selection there are inevitably some who become eliminated. In this case many hundreds of men, not all young, and many married and with children have been led by official and semi official statements

While the general practitioner can, by reading, keep himself reasonably *au fait* with recent work in the specialties, he can learn of advances in general practice only by contact with his fellow practitioners, and we feel that this method of postgraduate instruction merits a wider trial. The postgraduate dean of a university medical school might maintain a list of general practitioners willing to teach as they worked, and by introducing countryman to townsman, and Englishman to Scot, he might spread the personal advances of the few among the practices of the many. Recognition of this type of refresher course should be followed by the granting of subsistence allowance and remuneration of a locum tenens, which can already be claimed by those attending such courses in hospitals.

Finally, the system might be extended to the hospital worker, junior or senior. From the general practitioner the specialist might gain a new perspective, while the family doctor would learn, through his own cases, of the latest advances in the visitor's specialty.

REGISTRARS

SIR,—Your recent editorials do less than justice to the cause of the registrars. You appear to have lost sight of the fact that circular R H B (50) 106 makes a drastic cut in the numbers of doctors who are today giving good and mostly whole time service to the hospitals. It is not particularly the arbitrary nature but the extent of the proposed cut which is the cause of anxiety. You ignore the immediate issue—that this cut will drastically reduce the scope and quality of the already existing hospital and specialist services—as well as the fact that expansion in the future will be made more difficult.

The registrars are quite prepared to consider that there should be a proper review of the whole position. They are not likely to regard the Ministry's circular as a proper review, or to agree that adequate consultations have taken place with those responsible for the hospital services or those representing general medical services. Both these complementary aspects of the National Health Service would be considerably altered if the circular were carried into effect.

It is difficult to follow your arguments about "economic facts" (Nov 25). This circular simply proposes to cut the number of registrars by "upwards" of 1100. These registrars will be compelled to seek some other employment. Most will rightly wish to do so in their own country. No saving can be effected by transferring the pay accounts of these doctors to a different column in the National Health Service ledger. Moreover, it is difficult to persuade registrars of the economic necessity for this step when it follows within a few weeks the secret distribution of merit awards against which many distinguished voices in the profession were raised and whose total amount would go far to establish fresh consultant posts.

It is pointless to relate future registrar posts to the number of consultant posts likely to be available when the number of such posts is already inadequate for the work done¹ and much of it is therefore necessarily carried out by existing registrars. Visiting committees are already attempting to assess this need, and no reason is given for the necessity of taking this precipitate action in advance of their report. The proper preliminary steps would be to establish the number of consultant posts necessary to give an adequate service to the public even on the present standard of service, create the new posts involved, fill them from the ranks of the trained regis-

trars, and then consider what must be done to bring the number remaining into line with future possibilities.

The alternative measure proposed for staffing hospitals in place of the 800 senior registrars, most of whom are engaged full time, is the employment of part time general practitioners. It is quite clear that the necessary numbers do not exist today, nor are they likely to live in the places where they are needed. Indeed, it is disturbing that it can be suggested that there are doctors with the higher qualifications and necessary experience who are not doing more than part time work today in general practice.

In the appendix attached to this circular no mention is made of the fact that the clinical assistantships might be available to displaced registrars. Indeed, the only suggestions made are that the sacked registrars can either join the Army or leave their country. Moreover, the appendix gives examples of vacancies which exist today and which have existed for some time and which no present registrar has been tempted to apply for because the terms and conditions of service are not sufficiently attractive. The position was neatly summed up by the chairman of the Medical Priorities Committee, Lord Haden Guest: "The usual objections made to Service life, besides unfavourable pay, were that it cut a man off from his profession, limited his medical experience, and took him abroad. Then when he was between 50 and 60 it left him stranded with a smallish pension and nowhere to go. Much the same objection applied to the Colonial Medical Services."² Registrars would agree that the proper way to fill these jobs is to raise their standard and not to force doctors to accept them as an alternative to unemployment.

Dr Talbot Rogers's thoughtful contribution to your last issue is to be welcomed as suggesting a partial solution to one side of this problem. A number of registrars have always chosen the alternative of general practice of their own free will, and a considerable number have always known that they have this alternative before them if they find their attempts to specialise either uncongenial or unrewarding. What is new in this circular is that many registrars will be forced to take this course against their will. A number, too, who have every reason to believe that they would make good consultants from their experience of the work, are now to find themselves dismissed either for geographical reasons or because they have finished the prescribed course of training and no further vacancy exists to enable them to continue to give their best service.

It is probably correct to argue that the difficulties of entering into general practice hindered a number of registrars, particularly those in their earlier years, from making this choice. Nor can such reports as that of Dr Collings³ encourage these keen young men. However, Dr Talbot Rogers thinks that the main stumbling blocks to entering general practice are lack of suitable premises and methods of payment. These two difficulties must be overcome, but it is hard to agree that his solutions are revolutionary, they are simply novel. A much more revolutionary and none the less more acceptable solution would be to start the building of health centres where they are most needed and offer the choice of a salary as an alternative to capitation fees to those willing to work in them. It is not likely that a patchwork attempt to get other bodies such as R H B S to ease their consciences by contributing to the financial support of their displaced erstwhile servants will be satisfactory.

One other major weakness of Dr Talbot Rogers's approach is that if R H B S in consultation with local medical committees—i.e., the representatives of those already in practice—find that there is a suitable general practitioner already established, he is to get the available

SIR—The Gordian knot of excess registrars is being cut in high style. In any scheme whereby progress depends on selection there are inevitably some who become eliminated. In this case many hundreds of men, not all young, and many married and with children, have been led by official and semi official statements

to expect that there would be vacancies for nearly all in an expanding specialist service. Many have already trained for some years. Most are now to be rejected.

Is there not a less unjust solution? The intake of new registrars could be cut to a trickle, comprising only the most promising young recruits, for, say, three years, while the posts falling vacant would have time to absorb present registrars of proved efficiency. These men could meanwhile have the tenure of their present posts, or similar posts in other hospitals, extended for three years should they wish to continue.

Admittedly this would cause hardship among young men wishing to start specialising during the next three years, but at least they would not have started their training and would not have been led on by promises unlikely to be fulfilled. It would be the lesser injustice.

Leicester

DONALD MCGAVIN

SIR,—As there seems to be lack of knowledge and understanding of the work of the non-teaching hospitals as at present constituted, we feel that now is the time to state some of the facts.

The function of the non-teaching hospitals is to provide a complete hospital service for a given area. They are no longer "chronic institutions" but modern general hospitals with large numbers of acute beds and a rapid turnover. Since the war they have been developed to fulfil a most urgent need for hospital beds.

The development of the non-teaching hospitals has been made possible by the gradual formation of a registrar group, which is an integral part of the hospital staff and which cannot in any way be classified as solely trainee. These registrars are almost entirely responsible for a 24-hour emergency service and for that day to day care of the patients which is beyond the experience of the housemen. In addition they take a full share in the work of the outpatient and ancillary departments. Thus, registrars are essential to the efficient working of the non-teaching hospitals.

The consultants, deprived of the assistance of their registrars, will be faced with an impossible burden of acute and outpatient work, unless their number is increased, and such an increase is evidently not contemplated.¹ Part-time clinical assistants, whose loyalties are divided between practice and hospital, cannot be adequate substitutes for whole-time registrars. The alternative is to increase the work of junior house officers beyond the limits of their experience. For the patient this can only mean lowering the standard of his treatment, greater difficulty in securing a hospital bed, and increase in the length of his stay. This is one of the aspects which your annotation of Oct. 28 suggests may have to be ignored at present, but should this be allowed to happen there will be a reversion to the *status quo ante bellum*—which is surely a negation of the aim of the health service as far as it concerns the hospital service.

If the hospital service is to continue, its needs will have to be met. We suggest, therefore, that the establishment for registrars should be based upon the hospitals' requirements and on the optimum number of consultants, and that the full status of the registrar as a working member of the staff of the hospital should be recognised. Consultant posts should be increased over a period, and filled from the ranks of the senior registrars, either by extending the present tenure of this office, or by creating a new post of junior consultant to bridge the gap between registrar and full consultant.

The present lack of consultants is admitted, the remedy is to hand, and it is surely very shortsighted to reject it.

Walton Hospital, Liverpool

THE REGISTRARS

¹ See *Lancet* Oct. 28 1950 p 493

SIR,—The Ministry's memorandum¹ is welcome in that it provides a basis for constructive criticism. The plain truth is that by various devices the Ministry has, since 1945, encouraged medical men (mostly demobilised officers) to train for consultant appointments on the implied promise that appointments would be available for all who made the grade, it has created large numbers of established and supernumerary appointments to facilitate this training, and now, when there exists a vast pool of mature and fully trained would-be consultants, it blandly asserts that absorption for the majority is impossible and advises, in effect, their summary dismissal. The Ministry is fully entitled to second thoughts, albeit belated, in determining the numbers of consultants to be absorbed into a service which has to be paid for as well as provided, but it is not entitled to redress its past errors at the expense exclusively of that small but invaluable section of the profession which it now seeks to jettison, for there are other solutions.

It is right that the establishment of senior registrars should henceforth be closely related to the likely number of consultant appointments. In the Ministry's memorandum this is taken to involve a reduction from some 1400 to 600. Admittedly some of those to be cast off will not have made the grade, but this will not apply to many more who, being suitable for appointment, have nevertheless so far been unable to secure a consultant post. Can the country or the service afford to lose this latter group, numbering perhaps several hundred?

The number of consultant appointments available depends on the amount of work attaching to each. Part-time consultants may have up to nine sessions a week, but there is no obligation on regional boards or boards of governors to advertise appointments carrying the maximum number of sessions. Since July, 1948, however, the majority of appointments advertised have been full-time or maximal part-time at the option of the appointee. By revising their practice and arranging their appointments on a basis of 5-6 sessions a week, the boards could increase by 50-100% the number of consultant appointments available. If such a policy were pursued over the next five years *pari passu* with a more gradual reduction of senior registrar establishments, all suitable senior registrars might be absorbed into consultant posts. It is true that their salary from such appointments would be little more than their salary as senior registrars, but they would have their status and the opportunity of other income, and it is very probable that in five years' time, with an expanding service and a decreased senior registrar establishment from which to recruit new consultants, the number of sessions would be gradually increased. In any case, few of those affected would not prefer such an appointment to the threatened dismissal. This procedure involves no additional expenditure from public funds, but it will result in a larger number of young consultants with smaller hospital commitments, nothing could be better calculated to facilitate an adequate hospital service with fewer registrars.

The Ministry's memorandum states that 160 consultant appointments are likely to be made each year. How is this figure arrived at? Lord Moran has stated that there are 6200 consultants on the basis of a 33-year span of consultant life (from 32 to 65 years); the replacement figure is over 160 annually. This calculation takes no account of wastage through death or retirement, of additional posts or openings outside the service, or of the need to replace the natural wastage of senior hospital medical officers (it would appear that these comprise a further 2000,² calling for an annual replacement rate of about 60). If all these factors have been

¹ See *Lancet* Nov. 11 1950 p 537
² *Ibid* Oct. 28 1950 p 492

taken into account before deciding on the figure of 150, then the Ministry must be planning to concentrate more sessions with fewer consultants as replacement occurs, and thus, as I have suggested, is incompatible with an equitable solution of the senior registrar problem.

The memorandum calls for 1100 registrars and 600 senior registrars. If we allow for wastage, fewer than 550 registrars will compete each year for 200 senior registrar appointments, great allowance must also be made for the fact that many trainee consultants will want to do a registrar's appointment in a different specialty from that of their final choice—e.g., the gynaecologist and orthopaedic surgeon should certainly do some general surgery, and likewise the neurologist, chest physician, dermatologist, and anaesthetist should do some general medicine. Thus the appointment ratio from registrar to senior registrar grade is likely to be nearer 2:1 than 3:1. Is this enough? It certainly is not. The essential point is that under the new arrangements a senior registrar will have a clear run to a consultant appointment, subject to his working well his only doubt will be the place of his appointment. No individual will have lost much, and general practice will have gained, if after two years as a registrar a would-be consultant fails to get farther, indeed, the value of entering practice with such experience will only be really evident when boards have been persuaded to reverse their present policy of exterminating general practitioner hospital beds. What is important is that those responsible for selecting senior registrars should have the widest possible choice, comparable to that which appointments advisory committees now have in appointing consultants, for in effect that is what they will be doing. For this reason an arbitrary limit to the ratio of registrar to senior registrar appointments is undesirable once the senior registrar establishment is brought into line with the potential consultant vacancies, and acceptance of any low ratio will at once defeat the whole concept of competitive selection for consultants. In this connection, therefore, the only real change required is a scaling down of the excess of senior registrar to registrar appointments, and retention of senior registrar appointments only at those hospitals or groups of hospitals from which graduation to consultant status will be a *sine qua non*. The action which is needed is therefore fourfold:

1. An immediate working party to determine what consultant appointments can be made available within the next few years on the revised basis I have suggested, without significant increase in public expenditure.
2. Immediate revision of para 9 (ii) and para 10 of the Ministry's memorandum so that the reappointment of present senior registrars for further years will depend, not on the new establishment but on assessment of each individual as regards his eligibility for consultant status at the termination of his senior registrarship.
3. The progressive replacement of senior registrars by registrars as the former are appointed to consultant posts or eliminated by individual review until the number of senior registrars remaining falls to the new establishment.
4. The widest advertisement amongst registrar grades of the magnitude and highly competitive nature of the proficiency bar which will in future exist at the point of transition from registrar to senior registrar.

With these arrangements we could weather reasonably well the difficulties of the next few years. The hospital service would be little affected. A maximum number of would-be consultants will be given a chance if they are themselves prepared to accept the risk involved yet they will early on be brought face to face with their real obstacle. And finally we shall not have broken faith with those who are now at, or near, the end of a difficult road and have proved themselves worthy.

Lewisham Hospital,
London S E 13

A. CAVENDISH
Consultant Surgeon

SIR,—Either registrars do useful work, and therefore specialist officers in the hospital service should increase, or else they do not. If they do not, then the present situation is only a melancholy monument to the stupidity and dishonesty of politicians, medical as well as lay. The displaced men will have to take what help they can get from their better placed colleagues (by precedent it is likely to be little) and exact what retribution they can from the politicians—with special reference, perhaps, to the author of the gratuitous insult contained in paragraph 12 of the Ministry's memorandum.

If the other hypothesis is correct, and registrars actually do treat patients successfully, a wholesale dismissal of hospital staffs has many implications. At least three of these require urgent consideration.

1. Sacking hospital doctors will not finance the rearmament programme. At a rough estimate it will save, as one of your correspondents has already said, about 1000 times £1000 yearly, that is, £1 million. A due and modulated succession to consultant status might mean an annual expenditure, in ten years time, of £2½ million. The total cost of our health service is around £400 million a year—much of which is wasted. So dismissing hospital staffs is not only medical nonsense, but economic nonsense too, in this latter category, with all respect, I include your portentous leading article of Nov. 25.

2. It is doubtful whether in fact this relatively trivial sum will be saved. If patients are there to be treated, something must be done about their needs. The memorandum envisages the employment of suitably qualified general practitioners on a part-time basis. These men will need payment on a scale commensurate with their loss of practice, and part-time work is in any event expensive. Furthermore, I do not believe that as a rule, general practitioners can be efficient "sessional specialists," any more than I believe that the displaced senior registrars will be efficient general practitioners. It is therefore possible that in the end there may be no financial saving whatever, or, if there is, it will be more than outweighed by increased disability and loss of working time in the productive population, due to unsatisfactory hospital treatment.

3. The acceptance of such a policy as this is likely to be followed by a complete disruption of the hospital services, because, to put it vulgarly, the supply of mugs will dry up. Dismissing ex Servicemen like myself as paranoid malcontents and looking only to the future I see that the medical student of today is unlikely to qualify until he is at least 24. A year's compulsory house jobs, two years in the Forces, a year, now, as senior house officer—and he is 28. He is then expected to embark on an uncertain series of yearly appointments from any of which he may be sacked and from one of which (the registrar/senior registrar transition) he certainly will be sacked. His monetary and geographical future will not be sufficiently certain for any kind gentlemen to lend him money to buy a house and if he has children he will be evicted from his lodgings.

At the end of this fool's progress during which he will have been too busy to learn his job properly he will if he is fortunate start to earn rather less—or even much less—than the general practitioner round the corner and as the hospitals will remain understaffed, he will continue to work himself to death. If he fails at any point in his progression he will start all over again making a gallant assault although by now partly disabled on general practice—where openings are few or perhaps I should say well-defended.

Nobody but a moron would undertake this career of specialisation. My betters tell me that struggle was the rule before the late war. But if there was cut throat competition at least one could choose one's own weapons. Now the fight is under handicaps imposed from above and the general gladiatorial effect is enhanced by the periodic appearance in the arena of mad Ministry bulls (the Papal pun is nearly unintentional).

To sum up, the present Ministerial policy appears to be. Unnecessary and expensive treatment is immediately provided, necessary and cheap treatment we cannot afford. Like you, I find much to admire in the National Health Service, but if policies like this

are accepted by the leaders of the profession, the whole edifice is likely to collapse

Permit me to add one personal point. I do not write from any sense of individual grievance, for I am likely to be one of the lucky ones. As, however, I am superstitious, I beg your permission to sign myself

ANOTHER SENIOR REGISTRAR

SIR,—It seems to me that there is a logical fallacy in the Ministry of Health circular R H B (50) 106 from which all the trouble springs. A registrar or senior registrar is not only a trainee or student but also a working doctor essential to the National Health Service, and because a trainee has to leave the training ladder it does not follow that a doctor (the same man) has to leave the kind of work and position for which he has so far been found adequate

London, S W 19

E A BURKITT

SIR,—The three aspects of the matter are now clearly defined

1 The personal problem of the registrars and their families. This is unlikely to affect the issue. The registrars are not sufficiently numerous to form an effective pressure group, and appeals on compassionate grounds cannot be expected to have much effect.

2 The adverse effect on medical education. The universities and medical schools have probably sufficient margin to overcome this by improvements in their administration.

3 The lowering of standards of care for the sick. This is a very different matter and one on which the general public may be expected to have something to say.

The general structure of the hospital side of the National Health Service has now taken definite form, and its authors must be prepared to meet criticism.

There is nothing which falls so dead in the medical press as an attempt to start a discussion on principles of administration. The subject arouses no interest, and it is perhaps not surprising that it is difficult to detect any coherent body of principles in the hospital organisation that has now been established. One plausible explanation is that the Minister adopted the plan that Mr Wilfred Pickles found so successful for producing a good show—"Give them the money, Barney." Effective control of the money and everything else was handed over to the teaching hospital consultants, and all things considered it is a wonder the show is not worse. (It was Lord Clive who exclaimed, "By heavens, I stand astounded at my own moderation!") With the distribution of the secret merit awards, even the jack pot is empty and the money has come to an end. This would seem an appropriate moment to consider if it was well spent. From the imminent breakdown in the service this seems to be in serious doubt.

From the outset it has been assumed that an efficient consultant service could be provided by engaging consultants for a certain number of sessions per week. The fallacy of this assumption has been obscured by the fact that extremely competent registrars have been giving the 24-hour day and 7 day week service that the public needs. If the registrars are to be greatly reduced in number some alternative must be provided. The proposal in the circular that they could be replaced by part time clinical assistants is quite out of touch with reality.

The best suggestion is that a grade of assistant consultants should be established. Many of the senior registrars are well fitted to occupy such positions. This grade would not carry the objections which apply to the grade of senior hospital medical officer. The only serious objection would seem to be financial, and it is this consideration which gives pertinence to the question. Has the money been well spent?

Walton Hospital Liverpool

HENRY H MACWILLIAM

Parliament

How Many Registrars?

IN the House of Commons on Nov 22 Dr CHARLES HILL pointed out that the hospital and consultant service was provided by three groups of doctors—the specialist at one end, the junior house officers at the other, and in between the registrars who were training to become specialists. There were some 5200 specialists in this country. In the two senior groups of registrars there were some 2800 doctors at one or another level of the uncertain ladder of specialist status.

It had been decided reasonably, as Dr Hill agreed, that the number of registrars should be regulated by the probable number of vacancies in the specialist ranks, and it had been calculated, partly on the basis of the age of existing specialists, that 150 vacancies would arise each year for the next few years. This figure allowed for 30 additional specialist appointments. When the National Health Service started it was hoped that there would be available in all parts of the country a comprehensive specialist service. A modest beginning had been made. That the calculated annual increase in the number of specialists should be only 30 seemed to Dr Hill tragic. To fit this policy of a tiny annual increase in the specialist establishment, 1100 of the 2800 doctors now training to be specialists were to be swept out of the registrar ranks. It was sound policy to adapt the number of specialist training posts to the prospect of promotion, but what was happening now, no doubt for financial reasons, was a freezing of the specialist establishment at the present level, apart from this modest increase.

Under a circular sent out to all regional boards and boards of governors three quarters of the senior registrars would have to go as soon as possible after Jan 1, and also two thirds of the intermediate group. Under special circumstances some senior registrars could be kept on, but in general they would have to go. This was largely due, Dr Hill suggested, to the timid attitude adopted to the future expansion of the consultant services. Moreover the registrars were not only under training for consultant status, they were also doing an important part of the work of the hospital. The Ministry's circular suggested that the gap which their departure made should be filled by general practitioners on a part-time basis. Dr Hill said he would be the last to suggest that the general practitioner had not an important place in a hospital—indeed he thought that the G P's position should be stronger. But to suggest that on a part-time basis the G P could do the work of the senior registrars was sheer nonsense.

The registrar ranks had been swollen since the war in the belief, fostered by the Government, that there would be an expansion of the consultant service. Many registrars were men of 32 to 35 who had served in the Forces during the war. They had been training for specialist status ever since. But he did not want to put the case only on a personal basis. If the implied undertaking that there would be a consultant service everywhere was to be carried out, then an increase of establishment of 30 consultants a year was insignificant. The Ministry had calculated that the country needed 7500 whole time specialists, yet there were only 5200, most of whom were part-time. Dr Hill believed this timid attitude, combined with unwisdom in the mode of applying this policy, was not only dangerous to future hospital policy but would be damaging to the hospitals of the country from the early part of next year.

Although Dr Hill informed the House that he had given the Minister notice at 2.30 P.M. that day that he was going to raise this matter on the adjournment motion no representative of the Government was present and no official reply was given.

Nurses in Sanatoria

IN the House of Commons on Nov 23, Mr R J MELLISH, calling attention to the shortage of nurses in tuberculosis sanatoria, said that in the 15 sanatoria administered by the South Eastern Regional Hospital Board, of which he was a member, 521 beds were empty through lack of staff. Yet in this region men had to

wait on an average five months to enter hospital, and women from ten to twelve months. In the whole region, which catered for over 3,000,000 people, 24,000 were receiving tuberculosis treatment and 208 died last year.

One of Mr Mellish's objects in raising the matter was to try to remove the fear of infection which he believed was militating against the recruitment of staff. In response to the Minister's request the Bermondsey general hospital was anxious to open a ward for tuberculous patients, but though they had tried for three months to get a qualified tuberculosis sister they had failed. He urged that the General Nursing Council should insist that all student nurses should have 3 months' experience in a sanatorium as part of their training. The pay of tuberculosis nurses should be higher than the ordinary scale. If a proper appeal was made Mr Mellish felt confident that many more part-time helpers would come forward. A guarantee could be given that the danger of infection was remote.

Mr J E POWELL believed that the figures on the waiting lists were underestimated because doctors hesitated to add cases to the waiting lists owing to the delay in admission. He thought that they should go even further than the imposition of 3 months in a sanatorium as part of a nurse's general training. A nurse who had served a year in children's, fever, or mental nursing could offset that period against the length of her general training. That did not apply to service in a sanatorium and this was a deterrent to a nurse taking part of her training in such institutions.

Mr ANTHONY GREENWOOD said that adequate housing accommodation, especially for male nurses, was needed. He also deplored the lower status of tuberculosis nursing. As practical remedies he suggested that sputum mugs should be replaced by destructible cartons, that nurses should be freed from the duty of counting soiled bed-linen and clothing, that there should be facilities in all wards for boiling crockery and cutlery, that electrical appliances should be provided for cleaning wards.

Mr A BLEVINKSOP, parliamentary secretary to the Ministry of Health, said that when the National Health Service was introduced there were just over 4000 full-time and slightly more than 600 part-time nursing staff in sanatoria and tuberculosis nursing hospitals. At June 30 this year the number had increased to some 5300 full-time and 1000 part-time nursing staff. This improvement had led to an increase of staffed beds from 21,800 in 1948 to 23,300 at present. There were still 4400 unstaffed beds and 2900 more nurses were needed. One of the most potent factors in restricting the effectiveness of the campaign for more nurses had been the fear of infection, but the position had improved during the past year thanks largely to the advance of medical knowledge and the use of B C G vaccine, which was being made generally available for sanatoria and general hospital staffs, as well as in the domiciliary fields. Whitley councils had already agreed on improved scales of general pay for tuberculosis nurses. The Ministry were working out with the teaching hospitals plans for secondment of nurses from teaching and other hospitals to sanatoria. These arrangements would be on a voluntary basis, but they would be encouraged by the Ministry with the full support of the General Nursing Council on the basis of proposals carefully worked out by the tuberculosis subcommittee of the Central Health Advisory Council. The Ministry were anxious to secure the greatest possible accommodation for tuberculous patients in general hospitals provided that proper precautions could be taken against contacts. That meant either separate blocks, or at least separate ward accommodation.

Treatment of Tuberculosis

On Nov 24 in the House of Commons Mr G WILLIAMS pointed out that there were on an average 400 deaths every week from tuberculosis. Some people were dying without treatment, and others received treatment so late that there was little hope of recovery. Yet there were plenty of beds available abroad. Before the National Health Service was introduced local authorities were able to send patients abroad, paying half the cost.

At present the Dutch were sending patients to Switzerland and other places. We had 11,000 people waiting for treatment and yet no advantage was taken of foreign sanatoria. He estimated that we could send patients to Switzerland for treatment for £13 15s a week, exclusive of pocket-money. In Switzerland 1495 beds were available, and if there was difficulty in providing Swiss currency, France and Scandinavia offered alternative places for treatment. While the beds were available in these countries Mr Williams thought it was wicked not to use them.

Mr BLEVINKSOP said the Ministry were reviewing the provision of facilities for treatment of tuberculous patients in Switzerland, but all the information the Ministry had from Switzerland suggested that the contribution that country could make was much smaller than the figure Mr Williams had mentioned. Medical opinion varied about the value of treatment in Switzerland for particular types of this disease. The death-rate from tuberculosis had fallen from 23,550 in 1947 to 21,983 in 1948, and 19,834 in 1949. The figures for this year showed a continuation of this encouraging trend. Even though accommodation was short and the waiting-lists long, it was right to go on with mass radiography diagnosis in order to know where the disease was. Even in the home a great deal could be done to limit its spread. The Ministry were considering the administrative organisation of the health service in relation to some of these problems, both in tuberculous and other special fields. Their minds were by no means closed to any changes that might be necessary to secure more effective co-operation between all the agencies concerned.

QUESTION TIME

Merit Awards

Mr BEVAN informed Colonel M. Stoddart Scott that the Merit Awards Committee had so far recommended 1504 consultants for awards. It was not intended to publish a list.

Hospital Committees and Trade-union Membership

Sir WALDRON SMITHERS asked the Minister if the two circulars, no 13 and no 20, issued by the Whitley Councils, had received his approval, especially paragraph 3 (b) of circular no 20, which provided that members of a hospital consultative committee should also be members of a trade union—Mr A BEVAN replied: Yes, Sir. The proviso refers to members of a nationally recognised negotiating body. The application of the proviso is suspended for the present.

School Dental Service

In answer to a question Mr GEORGE TOMLINSON, Minister of Education, said the number of dentists employed in the School Dental Service at the beginning of June was equivalent to 734 full-time officers. For a complete service of dental inspection and treatment in which every child was seen annually and all children who required treatment received it, he estimated that a ratio of about 1 dentist to 3000 children would be needed. An additional 1150 dentists would have been needed last June to give such a ratio. Owing to the general shortage of dentists, however, it would be impracticable to achieve this for many years. His immediate aim was to get the service back to its 1948 level, when it was able to offer effective preventive treatment. For this purpose some 200 additional school dentists would be needed in England and Wales. He hoped that progress could be made in filling the deficiency as a consequence of the meeting of the Dental Whitley Council.

Public Health

Poliomyelitis

In England and Wales notifications of poliomyelitis during the week ended Nov 18 were: paralytic 110 (161) non-paralytic 39 (64), total 149 (225). The figures for the previous week, compared with which there was a total decrease of 76, are in parentheses. Uncorrected notifications for the corresponding week in 1947 and 1949 totalled 201 and 229.

Total uncorrected notifications for 1950 up to and including the week under review are 8121. The corresponding figures for 1947, 1948, and 1949 are 8076, 2165, and 6134.

Obituary

JAMES ALEXANDER MURRAY

M D, B SC EDIN, F R S

Dr J A Murray, one of the pioneers of experimental cancer research and a former director of the Imperial Cancer Research Fund, died at Hove on Nov 20.

James Alexander Murray, the youngest son of W Murray, of Diamond, Midlothian, was born in 1873. He was educated at George Heriot's College and at Edinburgh University. Before reading medicine he took his B SC degree, and later he worked in Germany with the eminent cytologist Boveri. Having qualified in medicine in 1899, he was awarded the gold medal for his M D thesis in 1907. Meanwhile he had spent some time as medical officer in a mental hospital and as a locum tenens in general practice in Lancashire. In 1903 he

(Eatonman)

was appointed assistant to Bashford on the staff of the recently formed Imperial Cancer Research Fund, with which he remained until his retirement in 1935. In 1915 he was appointed director in succession to Bashford. He was elected F R S in 1925.

Murray's earliest papers were on cytological subjects, but his best work was done in experimental cancer research. When he joined Bashford, Jensen in Denmark had lately shown that the transplantation of tumours in laboratory animals was a practicable and promising method of cancer research. Bashford and Murray followed up this lead with energy and

success. Already in 1905 in the second Scientific Report of the fund they had laid the foundations for the series of classical papers which, during the next few years, established the world-wide reputation of the laboratory as an outstanding centre of experimental cancer research. The staff was greatly increased and much of Murray's work was published jointly with his colleagues, but his personal contribution was large and important. He was a dexterous experimenter and an expert histologist. It was due in great measure to him that experimental cancer research in this country from the first developed on a foundation of sound pathology. He contributed to the massive third report (of 1908) important papers on the zoological distribution of cancer and on spontaneous and transplanted tumours of mice. Many of his observations remain unsurpassed and those early papers still repay close study. His paper, published in 1911, on Cancerous Ancestry and the Incidence of Cancer in Mice provided the first demonstration of a hereditary factor in the aetiology of mammary cancer in mice.

By 1914 transplantable tumours had been fully exploited and their limitations were well known to Murray. After the interruption due to the war of 1914-18, he turned his attention to the induction of tumours by tar, and he was among the first to show by careful clinical and pathological investigations that the new method was applicable to mice and that the resulting growths were malignant tumours. Though Murray continued to study tar tumours his papers became less frequent. His influence on cancer research, however, remained strong and wholly salutary. He was widely known as a distinguished investigator of unquestioned skill and integrity, his command of German, French, and, to a less extent, Italian helped to extend his influence and reputation abroad. At home he attended meetings diligently and felt it his duty to contribute to discussions and to criticise what he believed to be unsound. "Murray's criticisms," a colleague writes, "based on wide knowledge and experience, were shrewd, penetrating, and always sincere. Though latterly he might be accused with some justice of over caution, his conservatism was often justified and sprang from a deep sense of responsibility. He maintained a remarkably high standard of

integrity in both private and professional life and could neither understand nor suffer gladly those whose standards were less exacting. He took few pains to disguise his contempt for pretentiousness and hypocrisy, he was often brusque with the eminent and flippant with the pompous. Some pathologists who ventured a firm opinion on a specimen he showed at a meeting 'for diagnosis' were not over pleased to learn that it was a stained section of haggis. As often as not the puckish wit was turned against himself.

"Towards his subordinates he was kindly, unselfish and generous to a fault.

"Murray was a man with strong opinions and many amiable foibles. Under the self-conferred title of The Woolworth Engineering Company he delighted to make apparatus at negligible cost out of tobacco tins, plasticine bent pins, and the like. Some of the products were surprisingly useful, but his fireside microscope, for use in an easy chair, never reached the production lines. Whatever the subject of conversation Murray was apt to interpolate some wholly unexpected information from his remarkable memory, for he had read and travelled widely. In his prime he was a keen and successful golfer being at one time captain of the Sandy Lodge club. His early interest in zoology and cytology persisted, and he relaxed happily in the study of pond water, about which he knew a good deal. He took particular pleasure in association with amateur and professional microscopists at the Royal Microscopical Society, of which he was twice president. In 1949, at the last scientific meeting he attended, the society conferred on him its highest distinction, the honorary fellowship.

"Murray earned the respect and affection of all who knew him well, they will remember the quality of his work and character and mourn a friend of many-sided accomplishment and charm."

In 1927 Dr Murray married Miss Ethel Beere, who survives him. There were no children of the marriage.

GEORGE STUART GRAHAM-SMITH

M A, M D CAMB, F R S

Dr G S Graham Smith, reader emeritus in preventive medicine in the University of Cambridge, died at his home in Cambridge on Aug 30, at the age of 75.

He was educated at Clifton College, at Pembroke College, Cambridge, and at Guy's Hospital. He was captain of the Pembroke cricket XI and was given a university trial as wicket-keeper, and at Guy's he played cricket for the hospital. He was also a successful golfer and spent much time bicycling when bicycling was new.

In 1901, after qualifying, he returned to Cambridge "wishing to learn a little more about pathology which, with kindred subjects, appealed to him more than practice." In the department of pathology he worked with Dr L Cobbett, Prof Sims Woodhead, and Dr G H F Nuttall. Nuttall, who had arrived in Cambridge two years before to teach bacteriology, founded the *Journal of Hygiene* in the same year, 1901. These three men won Graham Smith's lasting regard and loyalty.

His account of Nuttall and the department during the first two exciting decades of the century (published in the *Journal of Hygiene* in 1938) helps the reader of today to realise the intense vitality of these men and their period.

In 1902 Graham Smith was appointed bacteriologist to the Cambridge borough council and demonstrator in clinical pathology at Addenbrooke's Hospital. In

1 In his will Dr Graham Smith directed that no detailed obituary notice should be published because so few with whom he was intimately associated during his more active period now survive. After discussion and due reflection it has nevertheless seemed proper Dr Graham Smith's wish having been made known to publish this account for many who knew him as a pioneer in bacteriology and hygiene will wish to see it.

1904 he became John Lucas Walker student, and he graduated M.D. in 1905. In 1902 he and Cobbett published a paper on an outbreak of diphtheria which they had studied in Colchester in 1901. Interest in diphtheria was very keen at that time, when both bacteriological diagnosis and antitoxin treatment were new, and in 1907 Nuttall and Graham-Smith published their substantial book on *The Bacteriology of Diphtheria*, nearly half of which Graham-Smith wrote. Collaboration with Nuttall seems to have determined the main direction of his research. In 1904, Nuttall published his classical *Blood Immunity and Blood Relationship*, in which Graham-Smith contributed the section on lower vertebrata and arthropoda and on the medicolegal use of the precipitin test in identification of blood.

In all Graham-Smith published more than 60 scientific papers. Papers on flies and their relationship with disease were the most numerous. Next came protozoal diseases (he described a parasite *Grahamella* in the blood of moles in 1905) then general bacteriological topics including his investigations of the growth-curve and of the duration of spore-viability then diphtheria, animal diseases, and other miscellaneous topics. His interest in flies was strong and abiding. Most of his later laboratory research was devoted to the study of their structure and behaviour. Flies amused him. He would describe their habits with a sympathetic exactitude which was inimitably humorous. In his last year or two he collected many passages relating to flies from the writings of poets ancient and modern and he derived special pleasure from an article entitled "From the Fly's Point of View," by Barry Pain.

From 1905 onwards Graham-Smith continued to teach bacteriology and took part in university affairs. As assessor to the regius professor of physics (1907-19) he was closely associated with Sir Clifford Allbutt. In 1919 he was elected fellow of the Royal Society. From 1919 to 1933 he was secretary to the faculty board of medicine. A successor in that office writes "He was one of the most useful members of the board because of his long association with it and his intimate knowledge of university procedure." Earlier he was secretary of the now long-forgotten subcommittee for tropical medicine and hygiene. Those who attended his bacteriology lectures for the Cambridge diploma in public health will remember the dry wit and keen interest of them. He also taught bacteriology for part II of the natural sciences tripos in its early days, and for many years he continued to give a few special and memorable lectures on such topics as plague and cholera, and, of course, the fly as a vector of disease. In 1923 he was appointed reader in preventive medicine and so remained until he reached the retiring age in 1940.

In 1939 he became editor of the *Journal of Hygiene*. His name first appeared on its cover in 1912, but unquestionably he had helped Nuttall with the journal almost from its start in 1901. His strong feeling of loyalty to Nuttall made him feel responsible for maintaining Nuttall's tradition and standard. Those who contributed articles during Graham-Smith's editorship will agree that the words he wrote of Nuttall apply equally well to himself. He considered that an editor has an educational function in addition to his duty of assuring the regular appearance and high standard of his journal. In fact much of his time and energy was devoted to the correction and improvement of papers and to correspondence with contributors. He advised and helped the young and inexperienced workers. As editor he exerted great influence on workers scattered all over the world.

Perhaps Graham-Smith's most widely known memorial will prove to be the memorials he has left to the work of others. The walls of the present department of pathology in Cambridge carry the pictorial record which he collected of the development of the Cambridge Medical School, with which he was so closely and for so long associated. During the last year of his life, while almost confined by ill-health to his house, he worked hard on the compilation of a more detailed written record of the department and school, on a history of early entomology, on the collection of his anthology on flies, and on an account of the history of the *Journal of Hygiene* which will be published in the journal.

Dr Graham-Smith enjoyed good stories, his own and other people's. He could build a good story out of small everyday observations, and he found something amusing in practically any topic. He set us a remarkable example of humility and of intense loyalty to his friends and teachers and to the principles of accuracy and veracity.

E T C S

CHRISTOPHER ROLLESTON

M.A., D.M. OXFORD, M.R.C.P.

Dr Christopher Rolleston's main work was done as medical officer of health in the small counties of Rutland and the Soke of Peterborough where he brought the health services to a high efficiency.

Youngest of the three sons of the late Prof. George Rolleston, F.R.S., each of whom in his own line left his mark on medicine, Christopher outlived his brothers Humphry Davy and John Davy by some years. At New College, Oxford, he took second-class honours in the physiology finals in 1900, and he entered Charing Cross with a university scholarship. After graduating M.B. in 1903 he held house-appointments there and at the Prince of Wales's Hospital Tottenham, before he became an assistant medical officer under the old Metropolitan Asylums Board. In 1909 he took his D.P.H. and the following year the M.R.C.P. In 1910 he was appointed M.O.H. for Rutland, and in 1914 he took up his appointment at Peterborough which he held until his retirement. His special interest in tuberculosis, which was reflected in his published papers continued in his retirement, and only a few weeks ago he contributed a trenchant letter to our columns (Oct. 21, p. 486) in defence of the tuberculosis services of the public-health authorities.

A fellow M.O.H. writes "Rolleston was a conspicuous member of the group of medical officers of health who pursued child welfare between the two great wars. A man of decided views and a keen debater, he was the author of many reports which always excited interest and generally argument. Apart from the interest he took in tuberculosis he will be remembered chiefly for the part he played in the great controversy over tonsils and adenoids, in which he took a middle line, arguing with great force against the excessive reduction of operations which followed Dr. Glover's exposition of their abuse. He belonged to the school which urged child welfare more from the pathological than from the physiological and social angles, but he could see all sides of the problems, and though inclined to be dogmatic, he was always logical. He will be much missed by his colleagues by whom his erudition and force were greatly appreciated."

Dr Rolleston died on Nov. 19 at the age of 73.

Births, Marriages, and Deaths

BIRTHS

CHALMERS—On Nov. 1st at Inverness the wife of Mr J. A. Chalmer—F.R.C.S.—a son.
FENTLEY—On Nov. 24 at Sydney Australia the wife of Dr D. M. L. Fentley—a daughter.
KENWAY—On Nov. 19 in Manchester the wife of Dr A. K. Kenway—a daughter.
KUROWSKI—On Nov. 21 in Liverpool to Dr Ellen Kurowski wife of Dr A. C. Kurowski—a son.
O'NEILL—On Nov. 12 the wife of Dr Desmond O'Neill—a son.
SPRINGETT—On Nov. 15 in London the wife of Dr V. H. Springett—a son.
UNWIN—On Nov. 22 the wife of Dr P. Unwin—a son.

MARRIAGES

KENDALL-BRODIE—On Nov. 23 at Oswestry James Gordon Kendall M.B. to Jean Rhaladr Brodie.

DEATHS

BROADLEY—On Nov. 23 in Sheffield John Broadley M.B. Lond. F.R.C.S.E.
ELLIOT—On Nov. 18 at Fleet Hants Andrew Elliot M.A., M.D. Edin. M.R.C.P. D.P.H.

MURRAY—On Nov. 20 at Brighton James Alexander Murray M.D. Edin. F.R.S. aged 76.
RUSSELL—On Nov. 2nd Henry Bret Russell M.D. Lond. M.R.C.P. aged 55.
SWAFFIELD—On Nov. 19 in London Walter Henry Swaffield M.D. Edin. F.R.C.S.E.
THOMSON—On Nov. 26 in Belfast William Willis Dalziel Thomson F.R.C.P. D.P.H.

Notes and News

R S M AND GENERAL PRACTICE

ON Nov 22 the section of general practice was inaugurated at the Royal Society of Medicine by Lord Webb Johnson, the society's president who welcomed the formation of the section as a notable step in narrowing the gap between general practice and the specialties. He felt, too, that this section would help to maintain the general practitioner's interest in academic medicine—an interest which easily faded in the hurry of the day's work. Dr G F Abercrombie, president of the section, remarked that an immense amount of medical knowledge was hidden away in the minds and the medical records of general practitioners. The new section would enable all such doctors to transmit this knowledge, and he called on every general practitioner to ask himself if he had some contribution to make.

CHEMOTHERAPY OF CANCER

AT a meeting of the Liverpool Medical Institution on Nov 16, the inaugural Florence Blair Bell lecture was delivered by Sir Stanford Cade, who declared that the main medical methods of controlling cancer, besides radioactive isotopes (which are more a biophysical than a biochemical means of affecting the rate of growth) fall into one of the following three groups: (1) cytotoxic poisons, (2) hormones, and (3) vitamins. Of the better-known cytotoxic poisons, nitrogen mustard, urethane, and the folic acid antagonists have been tried clinically in enough cases for their value to be assessed. Nitrogen mustard is now used nearly exclusively in the terminal stages of Hodgkin's disease, in some cases of myelomatosis, and sporadically in other tumours such as cancer of the lung, lymphosarcoma, and some highly malignant testicular tumours. The mustards are, however, not an alternative to the better established methods of treatment, such as radiotherapy, but an additional weapon which is of value when the tumour no longer responds to radiotherapy.

In Hodgkin's disease, nitrogen mustard prolongs life and leads to further, temporary, regression. A compound, R48, prepared in the laboratories of the Chester Beatty Institute under the direction of Professor Alexander Haddow has proved of value against, among other tumours, malignant melanoma. Urethane, whose introduction is due to the experimental work of Haddow and Sexton, has now been used for several years in chronic leukaemia and myelomatosis. The folic acid antagonist, Aminopterin, may have an effect on the blood count even in acute leukaemia; its action, however, is chiefly that of a powerful leucotoxic agent and at present it is mainly a research weapon.

The control of prostatic cancer by oestrogens, and of breast cancer by both oestrogens and androgens, is of fundamental importance since these substances act principally on the host. In a considerable proportion of cases which would previously have been untreatable, the tumour regresses, pathological fractures heal, fluid in the serous cavities is absorbed, and the patient is restored to near normal health and may live for an additional 2-5 years. It is reasonable to presume that other hormones may also be of value, and already adrenocortico-tropic hormone (ACTH) and Cortisone are used experimentally with some interesting effects. Sir Stanford Cade also referred to a trial of vitamin B₁₂ in various forms of cancer, especially with metastases in the liver, in bone sarcoma and in cancer of the mouth.

UNIT FOR PREMATURE BABIES

THE planning of the premature baby unit which was opened at University College Hospital on Oct 1 represents a move towards simplification of nursing technique in this field. There are no cubicles (except for septic cases) or incubators, and there is no air conditioning.

The unit, which can accommodate 12 babies, consists of two nurseries (one warm and one at hospital temperature), a duty room, an isolation room, a kitchen and a sluice. The warm nursery is maintained at 75°F by thermostatically controlled electric panels and the humidity is kept at over 60% by a steam kettle. Both temperature and humidity are constantly recorded on a Cambridge recorder—one of the many ways in which nursing duties have been reduced to a minimum. The cots (made by Hoskins and Sewell) are rather larger than the usual type and are provided with close fitting glass tops which allow the oxygen content of the air inside to

rise as high as 80%. Bags for hot water bottles are slung along the cot walls and so do not interfere with nursing procedures.

The babies are fed on breast milk provided by their mothers or from the hospital's own breast-milk bank, and an attempt is being made to simplify the preparation of the feeds—a very tedious task when performed under aseptic conditions. A modified 'Elcomatic' pressure cooker has been acquired from Platers and Stampers Ltd, and it is proposed to prepare the feeds under ordinary clean conditions once a day, to fill the bottles, and then to sterilise the filled bottles in the pressure cooker. If this experiment is as successful as preliminary bacteriological tests have suggested, much nurses' time will be saved.

With the co-operation of the London ambulance service, a member of the staff of the unit will fetch a premature baby anywhere in the London area at any time. A heated cot with oxygen supply is constantly ready for this purpose. Outside the London area, the same service will be offered if an ambulance is sent to fetch the nurse on call. Unfortunately the accommodation at the hospital is not sufficient to allow mothers to be taken in with their babies, but it is proposed to make arrangements for them to stay in the neighbourhood in suitable cases, so that they can feed their own babies.

ROYAL DENTAL HOSPITAL

AT the 34th annual clinical At Home of this hospital, held last Saturday, clinical cases illustrating the work of the various departments were demonstrated throughout the day, and the orthodontic department had a display of some of the newer appliances for treating malocclusion.

A colour film of a bilateral mandibular osteotomy, performed by Mr C Bowdler Henry some two years ago, was shown during the morning session. The operation, which was for the correction of extreme prognathism, was done by the 'closed' technique, and some recent photographs demonstrated the excellent cosmetic and functional result. This film was an example of colour photography at its best and should be seen by all concerned with faciomaxillary surgery. Later in the morning Dr A B MacGregor gave a talk entitled 'Facts and Fallacies, in which he expressed his views on controversial subjects including the ritual use of certain antiseptic drugs which are no longer employed in medicine and surgery. His remarks on the relative inefficacy of tooth brushes in preventing dental caries were opposed to orthodox teaching, but served their avowed purpose of stimulating thought on matters that are often taken for granted. The main event of the afternoon's programme was a brains trust, whose members were Mr N J Answorth, Mr B W Fickling, Mr J H. Hovell, and Mr H M Pickard, with Dr MacGregor as an able and witty question master. The topics discussed ranged from the serious to the not-so-serious—from the significance of rarefied areas of bone at the apices of teeth to the higher marriage rate among women with proclined upper incisors, and from the correct name of an obscure oral lesion to the best hobby for a middle-aged dental surgeon.

The hospital has recently been granted an achievement of arms by the College of Heralds, and drawings were on view showing the evolution of the design, with its ingeniously selected charges indicative of the close relation between dentistry and medicine.

WAR-HANDICAPPED CHILDREN

IN Europe alone, it is believed some 13 million children have lost their natural protectors. In a new report¹ by UNESCO Dr Thérèse Brosse tries to give some picture of what such figures mean, and also to show what is now being done to help. Though this is much it does not begin to be enough.

Many of the children are refugees, and the International Refugee Organisation estimates that nearly 4000 are entitled to its care, but that less than half are getting it at present. Many countries have their own colonies and schools for displaced or orphan children, while the Pestalozzi Village in Switzerland is a unique international school. The children live with their own compatriots as families in the various houses sharing their games and out of school activities with children of other nationalities. In many parts of Europe schools were destroyed or damaged and children are

¹ War Handicapped Children. Report on the European Situation. UNESCO 1950. Pp 142. 3s.

being taught in cramped dark quarters with no equipment, or are going without schooling. Often fatigue, inattention, and forgetfulness at school are caused by poor living conditions at home. Behaviour disorders are all too common, but generally disappear by degrees if the child can work and play in stable friendly surroundings.

Many children were maimed during the war, and even as late as 1947 children were still being injured in Vienna—by exploding mines—at the rate of one a day. Provision for maimed or disabled children varies in different countries, and is said to be particularly good at the Cité Joyeuse des Orphelins at Molenbeek in Belgium. Emotional readjustment is more difficult to achieve, especially when a child has been bandied about from place to place and has changed his language and even his nationality once or twice. Such children either lose all self confidence or become aggressive, especially when children living with their parents outside a refugee camp look down on those from within the camp when they meet them at school. The task of those looking after such deprived children is to give them the security which comes from ordinary family life. Experience in every country has been that a child stands up well to danger provided he is in the company of a trusted adult. But the sudden loss of the home and the ordinary ties, and above all the sudden death of the mother can injure the child gravely.

The report calls for international co-operation in restoring these children, injured in so many different ways, to confidence and health.

AMERICAN ACADEMIC GRANTS

THE United States Educational Commission in the United Kingdom offer Fulbright travel grants to citizens of the United Kingdom and Colonies to go to America for an academic or educational purpose such as study, research, or lecturing. Applicants must have a guarantee of financial support in dollars for their stay. Graduate students must show proof of admission to an American institution of higher learning and all applicants whatever their programme in America, must be definitely affiliated with such an institution. But applications may be made by candidates who have not yet concluded the above financial and institutional arrangements. Graduate students must intend to spend an academic year of nine months in the United States, and professors lecturers, and senior research workers at least three months. No exceptions to this condition will be made this year, and grants cannot be given for attendance at conferences alone. These travel grants are available for travel to America between June 1 1951, and May 31 1952. They will cover the cost of return rail and steamship fares between the candidate's home in the United Kingdom or Colonies and the destination in America. No allowances are made for dependants' travel. Further particulars may be had from the commission 55 Upper Brook Street, London, W 1.

United States government grants.—The United States government offers grants in dollars to assist faculty members at the university level, advanced scholars and research workers to visit the United States for the purposes of research or teaching in the year 1951–52. The fields in which applications will be accepted include science and technology. Application for one of these grants which will be awarded for not less than six months and preferably for twelve months will also constitute application for a Fulbright travel grant. Candidates must be British subjects resident in the United Kingdom and each applicant will be required to prepare a plan for study or a specific project which can be materially assisted by 6–12 months of research or teaching in the U.S.A. Candidates will be expected to establish their own affiliation with an American university or research institution. Application forms may be obtained from the United States Cultural Office Room 22 5, Grosvenor Square London, W 1. The closing date for applications is Jan 15 1951.

MEDICAL FILMS

A LIST of films of interest to pathologists has been published (price 2s 6d) by the Scientific Film Association. The association, which is preparing a new edition of its Catalogue of Medical Films, would welcome information on new films especially of the sort made for research purposes or intramural teaching if the authors wish them to be included in the catalogue. Communications should be addressed to the hon. secretary of the medical committee Scientific Film Association 4 Great Russell Street London, W C 1.

University of Oxford

On Nov 18, the degree of D.M. was conferred on D S Parsons.

University of London

On Thursday, Dec 14, at 5.30 P.M., at the Senate House, W C 1, Sir Stanton Hicks will deliver the Sanderson Wells lecture on Food and Folly.

University of Witwatersrand

Dr Grantly Dick Read has been appointed an honorary lecturer in the department of philosophy.

Society of Apothecaries of London

At a recent meeting of the court of assistants, over which Dr Frank Howitt the master, presided, A W Banks was clothed with the livery. The following were admitted to the freedom of the society by redemption:

H W Harvey P J Helliwell H P Winsbury White G H MacNab J B G Smith C A Keele L R Broster J A B Young T H Hills H F Turner F C Golding Sir Stewart Duke Elder A C Boyle A D C Boll H B S Warren H H Fouracre Barnes C J S O Mallet A J W Beard Lady Whitby A R H Hicks J H C Hill J H Hunt Selwyn Taylor R H Franklin, K A Latter E G Tuckwell, P A Tyser F R Bottler G R H Wrangham Ursula Shelley.

The following were granted the diploma of L.M.S.S.A. upon examination:

C S Paul H Davidson P S McClure D J Müller

Princess Tsa-hai Memorial Hospital

Mr S W Allinson, F.R.C.S., has been appointed medical superintendent and first surgeon to this hospital in Addis Ababa, Ethiopia, Dr Edward Davison first physician, and Mr H C Fletcher-Jones F.R.C.S., second surgeon.

Congress of Military Medicine

The 13th International Congress of Military Medicine and Pharmacy will be held in Paris from June 17 to 23. Further particulars may be had from the secretary general of the congress, Section Technique du Service de Santé 8 bis, Rue des Récollets, Paris X.

National Association for the Prevention of Tuberculosis

On March 16 and 17 a course for doctors will be held at 7 Drumsheugh Gardens, Edinburgh, 3, on B.C.G. vaccine. The speakers will include Prof Charles Cameron Dr W G. Clark Dr Agnes Macgregor Dr Ian Macgregor, Dr Marc Daniels, Dr I Mills Hall, and Dr K Neville Irvine. The fee for the course is 3 guineas. Further particulars may be had from the Scottish branch of the N.A.P.T., 65 Castle Street, Edinburgh 2.

Wireless Phototelegraphy Service

A doctor who wishes to have an urgent consultation with a colleague in another country can now telegraph a radiograph overseas through the Post Office—Cable and Wireless phototelegraphy service. The charge depends on the size of the photo and also the country of destination. It ranges from £1 10s for a small picture to Belgium or France to £15 for a large one to the United States. Particulars can be obtained at any Cable and Wireless office, the large post offices, or by telephone to London Temple Bar 1222, extension 282 and Monarch 8060 extension 305.

Society of Medical Officers of Health

At the annual dinner of this society held in London on Nov 23 Dr J M. Gibson again spoke of the depressing effect of the National Health Service Act on those engaged in public health—the theme of his presidential address (see *Lancet* Oct 28 p 491). It was not surprising he said, if public health workers felt that they had had inadequate recognition from the public and from the authorities and if their reaction to the Act had been one of annoyance and despair. Now however they were growing more hopeful the pendulum was swinging back. He was replying to a speech by Dr E A Gregg chairman of the council of the British Medical Association who had referred to the close ties between the two bodies and had pledged the support of the B.M.A. in the struggle of public health workers for fair treatment. Sir John Charles and Sir Cecil Wakeley replied to the toast of The Guests amusingly proposed by Dr Hugh Paul. Through changing times, Sir John said there always remained the fundamental concept of the medical officer of health as the adviser to his local authority and the watch dog of the community he served. This was work worthy of a man.

THE CHANGING FACE OF SURGERY*

SIR CECIL WAKELEY

K.B.E., C.B., D.Sc. P.R.C.S.

SENIOR SURGEON AND DIRECTOR OF SURGICAL STUDIES, KING'S COLLEGE HOSPITAL, LONDON SURGEON TO THE ROYAL MASONIC HOSPITAL AND THE BELGRAVE HOSPITAL FOR CHILDREN CONSULTING SURGEON TO THE WEST END HOSPITAL FOR NERVOUS DISEASES AND TO THE ROYAL NAVY

SURGERY as we know it may perhaps be termed a new profession, when compared with the profession of medicine by physicians. In the days of the ancients, operations of various kinds were performed, but in the early hundreds A.D., barbers, bathkeepers, mountebanks, and sow gelders were the people to whom the practice of surgery was entrusted. In their hands the art fell to a low level. In A.D. 529 St Benedict founded at Monte Cassino a monastery which became famous once again in the second world war. Here a rebirth of surgery took place. But in A.D. 1210 William of Salicet wrote "A wise surgeon will refrain from stealing while he is actually in attendance on a patient." Even as late as this the profession of surgery could hardly be called a noble one.

Although in 1295 Lanfranc held that "no man could be a good physician who has not acquired a knowledge of operative surgery, a knowledge of both branches is essential," surgery was retarded by prejudice and tradition. Even such men as Galen remarked "Surgery is only a mode of treatment." It was Pope Innocent III who said "Ecclesia abhorrit a sanguine."

In A.D. 1368, by the appointment of master surgeons, a small guild of surgeons within the City of London was officially recognised. This was the earliest recognition of surgeons becoming distinct from both barbers and barbers exercising the faculty of surgery. The first Act regulating the practice of surgery in England was passed in A.D. 1441, but the struggle between the barbers and the surgeons went on until 1540 when the two guilds became incorporated as the Barber Surgeons.

There were really three factors which held back the progress of surgery.

One was the knowledge of anatomy or the lack of it. The student of today may well be appalled at the amount of anatomy which he is expected to learn, but the practice of surgery nowadays is dependent upon a detailed knowledge of anatomy. For many years any effort to obtain bodies for dissection was frowned upon by the Church, and as late as the 18th century it was only by illegal means that even the bodies of criminals were obtained for examination.

The second was the incidence of sepsis, which was always a sequel to surgical intervention, death very often following even minor procedures until the researches of Lister resulted in antiseptic surgery, which has now been modified to aseptic surgery.

The third factor was the lack of adequate anaesthesia. Until Lister with antiseptics and Simpson with anaesthesia removed the two last obstacles, the operations by which reputations of great surgeons were made, were more or less confined to amputations and cutting for stone. Both these operations were performed with great rapidity, surgeons disarticulating at the hip joint in under a minute and removing a stone from the bladder by lateral lithotomy in under thirty seconds.

In the latter half of the last century what we now understand by the art of surgery took shape. Surgeons were able to open the abdomen. As time went on and anaesthetics developed, the brain was explored, the chest opened, and the scope of operations increased.

With the widening field of surgery there has been associated a more detailed study of the basic subjects of anatomy, physiology, and pathology, and in the last thirty years surgery has undergone changes which are related to discoveries and developments in the ancillary subjects. The discovery of the sulphonamides in 1931 was followed by the discovery and clinical use of penicillin, and later of streptomycin and the other antibiotics now under clinical trial.

The physicists have developed X rays and radium, and radioactive elements are being used in the investigation and treatment of patients. The biochemists have played their part too. Intravenous therapy with blood, plasma, serum, saline, and glucose saline is of ever-increasing importance in extending the ever growing scope of surgery. The importance of water balance in the body has now been recognised.

In this country anaesthesia has established itself as a full specialty, and has been improved to such an extent that surgery which could not be practised twenty years ago is now performed as an everyday procedure. The old arrow poison, curare, which was used by primitive people to kill their enemies, is now used by anaesthetists with better motives.

With the increasing average age of the population and the greater longevity of the race, with the help of better anaesthetics, better supportive treatment, and the use of antibiotics, more old people are now undergoing major operations and surviving without becoming a burden to the rest of the population.

UNDERGRADUATE TEACHING

Before the days of Lister surgical lectures were practically the only form of instruction for the students. Today set surgical lectures are not popular nor are they necessary. In their place lecture-demonstrations have come into vogue. Bedside teaching and outpatient teaching are of the utmost service to the student. It is only by coming into personal contact with patients that students can acquire a satisfactory knowledge of surgical conditions. The actual palpation of a lump or tumour will register far more on the cerebral cortex of the student than a well-delivered lecture.

APPRENTICESHIP

In earlier days the student was apprenticed to a surgeon, and there was a great deal to be said for this form of learning. There was a personal touch about this way of acquiring clinical knowledge and the added interest of seeing patients in their homes and thus becoming initiated into problems which nowadays are only met with after qualification. It is to be hoped that when the new Medical Act comes into force, making a year's postgraduate experience compulsory prior to registration, the qualified student will be able to take part of his year's postgraduate training with a general practitioner.

Apprenticeship puts the student on his mettle because he must rely on his clinical acumen rather than on all the ancillary aids which are ready at hand in hospitals. There is a tendency today to overlook clinical observation and to rely too much on X rays and pathological or biochemical tests in making a diagnosis. I very much doubt if the clinician today has the clinical acumen of the late Victorian physicians, who made their diagnoses without the aid of tests and were often amazingly accurate.

PROFESSORIAL UNITS

After the first world war the surgical professional units came into being and their number has been greatly increased since the second world war. There is a trend, however, for full-time professional units to become too academic and to lose touch with patients and their diseases. There seems to be a tendency for teaching

* Opening address delivered at the Westminster Hospital Medical School on Oct. 2.

Memorial to Lord Rutherford

The Royal Society is proposing to establish lectures and scholarships in memory of Lord Rutherford. Donations may be sent to the Rutherford Memorial Fund at the Royal Society, London, W 1

Pathological Films

Some films on pathology will be shown at a meeting of the medical committee of the Scientific Film Association at 1, Wimpole Street, London, W 1, on Dec 11, at 5 p.m., when Prof Robert Cruickshank will be in the chair

Drugs and Spectacles

An appendix to the report of the Committee of Public Accounts shows that in the year ended March 31, 1950, payments under the National Health Service to 14,260 pharmacies in England and Wales amounted to just over £30 million—including £14 million for ingredients, £9½ million for dispensing fees, and £4½ million for "on cost" allowance. This total represents slightly less than twelve months' earnings. During the same period opticians received £4½ million for sight testing, and £17 million for the supply of spectacles

Potency of Streptomycin

Under the Therapeutic Substances Amendment Regulations, 1950, the tenth schedule to the Therapeutic Substances Regulations, 1931, is amended, from Dec 1, to require that streptomycin with a potency of less than 600 units per mg shall not be issued. Hitherto the minimum potency has been 300 units per mg. The requirement that a solution of streptomycin with a potency of less than 2000 units per ml shall not be issued has been deleted from the schedule, since this requirement is no longer necessary

Industrial Injuries Certification

New regulations which came into force on Nov. 28 modify the rules for medical certification, and for claiming injury benefit under the Industrial Injuries Act. A doctor may now give special intermediate certificates (the certificates used where incapacity has already lasted at least four weeks and is likely to be prolonged) at intervals of up to four weeks, even though he is seeing the patient more often. Claims to benefit may be made and dealt with on the strength of these certificates, in advance of a further certificate confirming that the patient did in fact remain incapable of work throughout the period as forecast. Similar arrangements have already been made for certification, under the National Insurance Act, for sickness benefit

On Nov. 15th, Sir James Learmonth was invested with the insignia of a chevalier of the Legion of Honour

The third volume prepared in connection with the 6th International Congress of Pediatrics, held earlier this year in Zürich, is now complete. The three volumes, which constitute the transactions of the congress, may be obtained from the general secretary's office, International Pediatric Association, Kinderspital, Zürich 32, for 25 Swiss francs, or 27 francs if bound together

Appointments

FITZGERALD P. J. LRCP, DPH, asst. county M.O. and M.O.H. Willenhall Staffs

FLEMING, R. A., OBE, M.S. Durh. FRCS, lecturer in anatomy, Kitchener School of Medicine and asst. surgeon, Khartoum Hospital

HILL, I. M., M.S. Lond. FRCS, consultant thoracic surgeon, Grove Park Hospital

PARSONAGE, M. J., M.B. Manc. MRCP, DCH, asst. physician, department of neurology, General Infirmary at Leeds and consulting neurologist to hospitals under the control of the Leeds regional hospital board

SUTCLIFFE, MARY, M.A. M.B. Camb. DPH, deputy divisional M.O. for south eastern division of Surrey

WHITTICK, J. W., M.B. Edin., director pathology department, Royal Cancer Hospital London

Brook Hospital, London

Consultant Thoracic Surgeons

With the increasing average age of the population and the greater longevity of the race, with the help of better anaesthetics, better supportive treatment, and the use of antibiotics, more old people are now undergoing major operations and surviving without becoming a burden to the rest of the population.

UNDERGRADUATE TEACHING

Before the days of Lister surgical lectures were practically the only form of instruction for the students. Today set surgical lectures are not popular nor are they necessary. In their place lecture-demonstrations have come into vogue. Bedside teaching and outpatient teaching are of the utmost service to the student. It is only by coming into personal contact with patients that students can acquire a satisfactory knowledge of surgical conditions. The actual palpation of a lump or tumour will register far more on the cerebral cortex of the student than a well delivered lecture.

APPRENTICESHIP

In earlier days the student was apprenticed to a surgeon, and there was a great deal to be said for this form of learning. There was a personal touch about this way of acquiring clinical knowledge and the added interest of seeing patients in their homes and thus becoming initiated into problems which nowadays are only met with after qualification. It is to be hoped that when the new Medical Act comes into force, making a year's postgraduate experience compulsory prior to registration, the qualified student will be able to take part of his year's postgraduate training with a general practitioner.

Apprenticeship puts the student on his mettle because he must rely on his clinical acumen rather than on all the ancillary aids which are ready at hand in hospitals. There is a tendency today to overlook clinical observation and to rely too much on X rays and pathological or biochemical tests in making a diagnosis. I very much doubt if the clinician today has the clinical acumen of the late Victorian physicians, who made their diagnoses without the aid of tests and were often amazingly accurate.

PROFESSORIAL UNITS

After the first world war the surgical professorial units came into being and their number has been greatly increased since the second world war. There is a trend, however, for full time professorial units to become too academic and to lose touch with patients and their diseases. There seems to be a tendency for teaching

* Opening address delivered at the Westminster Hospital Medical School on Oct. 2.

and attention to be directed to those whose sole object is to pick out a small aspect of surgery and beat it until it is dead, and to take teaching away from those who are practising surgery as a full time occupation, the very people who are continually in touch with patients and their diseases, and who are therefore perhaps the better able to teach because their knowledge is more practical and less academic

Whole time surgical professors are apt to spend the greater part of their day attending university meetings, and therefore they have less opportunity for actual teaching and operating than their part time colleagues

Part time professors of surgery have in the past century been pioneers, for it is from them that advance in the art and practice of surgery has sprung. Such men as Lister, Fergusson, Macewen, Stiles, and Watson-Cheyne all held professorial surgical chairs, but they gave only half their time to these appointments. They came into contact with the practitioner, did consultative practice, and were in constant contact with their professional colleagues. To my mind any real advance in surgery will come from the part time men rather than the whole time surgical professor

SPECIALISATION

Specialisation in surgery is good up to a point, but there is a real danger of developing the ultra specialist who will only perform one type of operation. Such a state of affairs is bad for teaching and makes for little progress. There is a tendency to view a patient with ultra specialist eyes and only see a minute part of the anatomy instead of considering the patient as a whole. How often has a special operative procedure been performed on a patient in whom a far more serious condition has been overlooked because a careful general examination has not been carried out.

It is important that surgeons on the staff of teaching hospitals should remain general surgeons, but it does not matter if they have a hobby—for instance gastric surgery, thyroid surgery, or urological surgery. General surgeons should have a sufficient variety of cases to give the students a general outlook which is essential. It is, I think, agreed that there should be in teaching hospitals 5 beds per clinical student in general medicine and general surgery, but I wonder how often this obtains today.

WAR AND SURGERY

There has always been a relationship between war and surgery. Many of the famous surgeons of older times were military surgeons before they became well known in civil life.

Progress in surgery occurs during great wars because the surgeon has such a wealth of material coming under observation and review. The lessons learned in wars are often of great value in civilian practice, this is especially so with regard to traumatic lesions. In this mechanical age the treatment of injuries to the body is of the utmost importance. During wars surgical knowledge is pooled and made available to vast numbers of surgeons. This was especially noticeable in the second world war when the War Wounds Committee of the Medical Research Council did a great service to the medical personnel of the fighting forces of Great Britain and America. The use of blood transfusion, of penicillin, and of early evacuation by air were developments which will not be easily forgotten by medical men in the Services. Every branch of surgery made progress during the last war, but perhaps the most outstanding advances were made in the treatment of nerve injury and the surgery of the heart and great blood vessels.

EARLY AMBULATION

Today the patient is no longer allowed to become an invalid because he or she has had an operation. Early ambulation has proved its worth both in the young and

old and has lowered considerably the incidence of post operative thrombosis and embolism. At the commencement of the present century elderly patients suffering from fracture of the femoral neck did not die from the injury but from pneumonia due to enforced rest in bed. Today early operation, early ambulation, and the use of penicillin have removed most major complications.

Early ambulation has put a different complexion on the bad risk patient, for he benefits not only physically but also mentally. The stimulating effect of early ambulation on an obese female patient following cholecystectomy has to be seen to be believed. There is less likelihood of pulmonary collapse, inertia of the abdominal muscles, and circulatory failure, and there is in addition the desire to get well quickly. The old fashioned procedure of 14 days in bed after an operation simply led to atrophy of the muscles, and distension of the intestines, with constipation and depression as a result.

Modern physiotherapy goes hand in glove with early ambulation. Before operation the patient is taught how to breathe properly and how to make use of the abdominal muscles. This preoperative preparation has a very definite beneficial effect on the patient who will co-operate after the operation and use his abdominal musculature and so reduce the incidence of complications.

THE PUBLIC AND THE PRESS

Before leaving the subject of postoperative after treatment it might be well to consider how much a patient should know.

Although the public require to be educated in certain aspects of disease—especially in cancer—yet we must always remember that there is a danger of the press and the public knowing too much. Moderation in all things should be the ideal. Instruction in the early signs of cancer may be justifiable and important, but it would be a tragedy if we were responsible for creating a national cancer phobia among the population.

When the mystery goes out of surgery the patient often loses much of his coöperative power and confidence in his full recovery. Human beings are individuals and require treating as such. Some will benefit from a description of the operation performed upon them, while such knowledge will transform others into nervous wrecks, the surgeon must decide how much knowledge is justified in each individual case.

Confidence is the sheet anchor as far as the patient is concerned, once confidence is established he will cease to worry and the surgeon will have little difficulty in getting coöperation throughout any form of treatment that may be necessary.

SURGERY OF THE FUTURE

To those starting on a surgical career it may seem that operations go according to plan. Extensive operative procedures are seen to cause a minimum of inconvenience to the patients, owing to blood transfusion, gastric suction, and the preoperative and postoperative use of vitamins and drugs such as vitamin K and heparin, yet you must remember that these are recent innovations in surgical treatment and rarely a year passes without the introduction of something new. Surgery has by no means arrived at its zenith and further progress is not yet impossible—although it may well be that future research will eliminate some forms of surgical operations and that some diseases now treated surgically will be cured by intravenous drugs or other forms of treatment.

Surgeons of the Westminster Hospital have played an important part in the world of surgery and have contributed their quota to the changing face of the profession of surgery. To mention only a few, Walter Spencer, Rock Carling, Tudor Edwards, and Stanford Cade are men of whom you should all be proud.

THE PATIENT AND HIS DISEASE *

A E CLARK-KENNEDY

M.D. Camb., F.R.C.P.

PHYSICIAN TO THE LONDON HOSPITAL AND DEAN OF THE
MEDICAL SCHOOL FELLOW OF CORPUS CHRISTI COLLEGE,
CAMBRIDGE

In my first lecture I pointed out that the human body is the product of the plan laid at its conception and the environment in which it develops and is subsequently maintained. I said that the brain permits the development of consciousness, and that consciousness permits the development of mind, which evolves under the stimulus of experience, the brain conditioning the process. From that conception, I went on to review the risks to which human beings are exposed. Faults in the genetic plan may interfere with the development of the body and through the brain with the evolution of the mind. Adverse factors in environment may act on, and stimulate reactions by, the body, leading to pathological processes of the body which may interfere with its structure and functions, and if the brain is involved, with the structure and functions of the mind. Adverse factors in environment may also affect the mind directly through the organs of special sense and the understanding, leading to pathological processes of the mind. But it is an assumption to suppose that the human mind will ever be explained entirely in terms of the structure of the brain and the experience through which an individual passes. All men feel free to run their bodies into danger or deliberately protect them from risk.

Pathology of Body and Mind

Primary pathological processes of the body, if they affect the brain or any function of the body on which the brain depends, lead to abnormal reactions of the mind. They can weaken the power of the will, alter behaviour, cause confusion of appreciation of events in space and time, and modify emotional feeling. Primary pathological processes of the mind (which cannot exist apart from the body) may have a profound effect on the body. In conversion hysteria subconscious wish fulfilment interferes with physical function through the skeletal motor nervous system. In anxiety states repressed emotion interferes with physical function through the autonomic nervous system. Thus far, disease might be comprehensible in terms of Cartesian or Platonic dualism. A rider can normally control his horse, but a bad horse can gain control of its rider, and a bad rider can upset a perfect horse.

Many clinical conditions, however, are not to be explained so simply. They cannot be attributed to any known pathological process of the body interfering with the structure and functions of the brain on which the mind is based. Nor can they be attributed to any pathological process of the mind interfering with the structure and functions of the body. They cannot in fact be explained in terms of a simple dualistic hypothesis of body and mind. Both body and mind seem at fault or in some way peculiarly related. Take for example, the functional psychoses to which I have already referred. We are all liable to be depressed by unhappy circumstances, and physical disease modifies our emotional reactions to some extent, but in some people attacks of depression of mind associated with depression of physical health (which defies exact analysis) may occur again and again for no apparent reason and sometimes alternate with phases of excitement. It is true that disorder of mind dominates the scene, but these

attacks exhibit in many respects the features of physical disease. Moreover, a family history of mental instability and an association with certain physical types both point, as I said, to a genetic peculiarity in the structure of the brain which, we must suppose, has so conditioned the development of the mind (to separate body and mind artificially in order to try to arrive at some concept which our own minds can grasp) that it is peculiarly liable to react emotionally to ordinary experience, while at the same time the development of the mind in this way has so conditioned the subsequent maintenance of the body that the mind is peculiarly liable to succumb through the body to physical disease. In other words, we must invoke the psychosomatic concept of body and mind developing together, each reacting on, and reacting back on, the other, a view borne out by the tendency of cases of this kind to progressive mental deterioration suggesting further changes in the underlying brain as experience of life increases. Do we not see the same kind of thing in epilepsy?—the genetic tendency to fits, and then the progressive deterioration of the mind under the stress of mental and physical experience.

Similarly, every normal person tends to suffer to some extent from physical symptoms due to sympathetic stimulation when emotionally upset, and many are also liable to headaches or attacks of migraine or giddiness under similar circumstances. But these changes are transitory and leave no structural consequences behind. Some people, on the other hand, seem to be so constituted that emotional disturbance may precipitate thyrotoxicosis, leading to rapid loss of weight or so sensitise their bronchioles to peripheral stimulation that they start to suffer from asthma which may lead to heart failure eventually. In others, emotional states are associated with increased irritability of the skin, predisposing to structural change, while the association of characteristic emotional mental states with simple ulceration of the stomach and duodenum and ulcerative colitis is probably significant. We are driven to conclude, I think, that in these patients (in so far as our own minds can visualise psychosomatic development) the body has so conditioned the development of the mind, and the development of the mind has so conditioned the subsequent growth and maintenance of the body, that they are particularly liable to succumb physically to adverse physical factors or to emotional stimulation. Structural changes now supervene which are not produced in more normal people unless physical factors act more strongly—thyrotoxicosis in acute infection, for example, and true allergic asthma. Clinical experience, therefore, leads us to abandon our dualistic view of the body mind relationship, and compels us to conclude, as I have said already, that body and mind are different aspects of one underlying reality which like energy and matter, form and substance we cannot directly apprehend, our minds being so constituted that to us body and mind, like energy and matter, inevitably appear distinct.

Further, does the mind play no part in the pathogenesis of diseases associated with typical structural changes which are generally regarded as of an organic nature, although we do not yet understand their causation? For instance, is it possible for an unwanted pregnancy to precipitate disseminated sclerosis or for a sudden shock to lead to cardiac infarction? Can a man die of a broken heart or be killed by business worries? Could the news of Austerlitz have killed Pitt? Again the association between emotional shock and organic disease seems too common sometimes to be attributed merely to chance, and there is certainly no theoretical reason why operations of the mind should not predispose the body to succumb to adverse physical factors in environment or even lead to structural change in it direct. The transmission of impulses across synaptic junctions and the action of nerves at their endings are both due to the

* The second Croonian lecture for 1950 delivered before the Royal College of Physicians of London on May 11. The first was published on Dec 2.

formation of chemical substances, and, the body being a chemical structure, chemical change, even to this extent, is fundamentally structural change. Moreover, emotional and mental stress are both known to influence endocrine secretion, and endocrine secretion has a profound effect on structure and function. Besides, if shock can turn a man's hair grey, why should it not lead to degenerative changes in his coronary arteries? But we must not expect regularity. No two people have the same constitution, and constitution is basically physico-chemical. One man's body, it seems, is like a house built on the sand. He is predisposed to succumb physically to mental stress if subjected to it on a sufficient scale. Another man appears to be made of stronger stuff. The rain descends, and the floods come, and the wind blows. But his house falls not. It is founded on a rock.

The Nature of Disease

There is no absolute dividing line between health and disease. Normality is only that which is most common. Constitutional strength merges into average health, and average health through constitutional weakness into disease, the body being, as I have already pointed out, a balanced self-regulating machine permitting consciousness, dominated by mind, and capable of adaptation to a greater or lesser extent to demand on function from within and change in environment without. But there are limits to this process of adaptation. Disease, as I see it, is that condition of a person in which action on his body, direct or through his mind (which can influence to some extent the structure and function of the body), or action on his mind, direct or through his brain (which conditions the development and reactions of the mind), stimulates reactions by his body and/or mind, and then these together lead to alteration of structure or disturbance of function with the result that eventually he starts to complain of symptoms or discovers signs in his body, or his friends notice an alteration in his appearance or complain of some change in his behaviour. Nevertheless, even a definition of this length is far from "watertight," and I doubt that any definition could be framed which would satisfy everybody. In brief, if you prefer it, disease is that condition of a man in which genetic faults, on adverse factors in environment, or both together, are interfering with the normal balance of the machinery of his body and/or mind on which his adaptation to environment depends.

Ill health can therefore be understood to some extent, and usually understood sufficiently for practical purposes, in terms of its causes, which we can sometimes discover, and in terms of alteration of structure and disturbance of function, which we can often observe. In some conditions, however, it is necessary to think in terms of the unseen chemical machinery which underlies all forms of structure and function, and for a more profound understanding of disease a synthesis of structural, functional, and chemical concepts is necessary, in the same way that a synthesis along similar lines is required for understanding the nature of man himself. But it is doubtful if we can ever hope to understand disease completely even in chemical terms. There can be no disease without a patient to suffer from it, in the same way that there can be no mind as ordinarily understood without a body to maintain it. Every disease, we must admit, is an integral part of a man, the product of heredity and environment, in the same way that the man himself is the product of his heredity and his environment. Diseases divorced from patients are abstractions from reality, the descriptions in the textbooks being compound pictures of a large number of similar observed reactions. We do not understand the nature of a man, particularly the relationship which exists between his mind and his body. Whence it follows that we cannot really under-

stand the nature of his disease which is so essentially a part of him. Therefore, although medicine must use science freely, it cannot ever be wholly scientific, as some would make it if they could. It must always remain to a large extent empirical, compelled again and again to deal in a practical way with much which we do not understand. Many would say that for this reason it must always to a large extent remain an art.

Man has changed little down the ages. It is his diseases which have altered with the passage of time, owing to variation in the micro organisms pathogenic to him, and the use which he has made of his mind to increase his knowledge and modify his environment. Clearly diseases cannot be ready-made entities which overtake us and which can be neatly classified and labelled as their Latin names suggest. Rather, a little thought reveals that they must be reactions (outside the average which determine our ideas of normality) between a man's genetic origin (no two men have quite the same genetic origin) and his environment (no two men have quite the same experience). They also depend on the use which the individual makes of his mind, and at this level adverse physical factors may not act adversely. (It is exceedingly doubtful if any man would flourish long in his particular Utopia.) But there are no absolute dividing lines in this three-dimensional continuum. Excessive demand on normal function merges imperceptibly into constitutional disease, due to normal demand on function of a body or mind weak for little understood genetic or environmental reasons. Constitutional disease merges imperceptibly in one direction into psychoneurotic disease due to adverse factors in environment interfering with the development of a mind based on a brain somatically weak, and in the other into organic disease due to adverse factors in environment interfering with the development or maintenance of a body somatically weak for genetic reasons. Psychoneurotic disease and organic disease merge imperceptibly into psychosomatic disease in which the constitution of the patient is such that his body is predisposed to succumb to emotional stress or his mind to physical ill health. Psychosomatic disease, as thus defined, merges into organic disease in which little understood genetic or acquired factors conspire to produce structural and functional abnormality. Organic disease of this type merges into organic disease due to definite genetic defects or isolated adverse factors encountered by mischance in man's environment, or more often to some combination of genetic and environmental causes. This conception may well be wide of the mark. Nevertheless, it must be nearer the truth, I maintain, than the conception of diseases as distinct and isolated entities, necessary though that simplification must often be for practical purposes and for exchanging experience with one another.

Certain diseases, however, stand out as fixed points in this continuum, like the main peaks in a mountain range. These are the peculiarly characteristic reactions between man and his environment which we meet in practice occasionally and the more common reactions which we encounter almost every day, although it must be remembered that no two cases of what we call the same disease are ever really quite identical, because they are the reactions of two individuals constituted differently to a cause which is probably operating slightly differently in both cases. In some, such as diabetes and endogenous depression, a particular disorder of function dominates the scene and gives a disease its name, structural changes being absent almost altogether; in others, such as carcinoma and the reticuloses, there is a characteristic alteration of structure, the functional disturbance produced not being particularly characteristic. In a third type, characteristic structural change and typical

functional disturbance are both in evidence, as in rheumatic heart disease and hypertensive failure. Thus many diseases, within the sense defined, can be recognised at sight, and appear to "breed" true to type like birds and beasts and flowers.

Diagnosis

Sometimes, therefore, diagnosis is empirical, based on observation and experience, the pathological process and disorder of function from which a patient is suffering being obvious at sight. Under these circumstances no conscious processes of thought are necessary, and, as experience increases, clinical pictures as a whole can often be recognised without thinking, entirely from experience. At other times diagnosis is rational, based on reason, on the application of systematised knowledge and the accumulated experience of disease of different types to the clinical picture presented by the patient. More often it is partly rational and partly empirical. It depends on a combination of reason and experience.

Every patient who comes complaining of symptoms must be suffering from some alteration of structure or disorder of function of his body or some disturbance of his mind. In one case it may be due to constitutional weakness but might equally well herald the beginning of organic disease. In another a primary pathological process of his body may be interfering with the working of his normal mind or a psychoneurotic reaction of his mind interfering with the working of his normal body. Clearly therefore the casual division of patients into organic and "functional" in hospital practice, where it is mainly a question of spotting the former and disclaiming responsibility for the latter, will not stand analysis, and it will not even work in general practice where these so-called "functional" cases take up most of every doctor's time. Under these circumstances diagnosis must be much more accurate than that, and consists so often, not in finding a label which will fit a patient into the book, but in forming a concept, one to which it is often hard to give a name, which must be carried in the mind. Every sick man, I maintain, must be fitted for a practical purpose into his approximate place in our minds in the continuum of human disease which I have endeavoured to describe. Therefore, some method of thinking is essential, and in a difficult case, so often the one in which the patient tends to dismiss his symptoms as unimportant, disorder of function and pathological process should be deliberately divorced. What alteration of structure or disturbance of function is responsible for these symptoms and these signs (if any can be found to help)? What is the underlying pathological process responsible for their production in this particular person?

Some symptoms are clearly of a mental nature. The patient complains of anxiety, depression, or inability to concentrate. Others are subjective bodily feelings. He complains of exaggeration or diminution of a sensation to which he is normally accustomed, or of a new and arresting sensation which he may never have experienced previously. A third group of symptoms includes irregularities of normal function. A fourth comprises structural changes which the patient has discovered for himself. Symptoms of this kind are self-discovered signs which can be confirmed on examination, when further signs are often found. (The only true symptoms are subjective sensations which have no counterpart as signs, and the only true signs objective changes in the body which a man cannot well discover for himself, a distinction without any particular significance.) But, as we all know, the interpretation of a symptom or sign in one patient may be entirely different from its interpretation in another, and the same symptom or sign may suggest failure of function in one patient and overaction of function in another. In most cases, however, the

interpretation of symptoms and signs in one direction makes better sense than their interpretation in any other, and suggests that the patient is suffering from failure or overaction of this or that function or that the structure of his body has become altered in this or that manner. Moreover, if they are interpreted correctly it is usually possible to decide which are manifestations of some alteration of structure or disturbance of function due to the direct consequences of adverse action on his body, and which are alterations of structure and disturbances of function due to reactions by his body tending to conserve his life and promote his recovery. When their interpretation fails to make anatomical or physiological sense, signs and symptoms must be a product of the mind.

The nature of the underlying pathological processes, unless the history supplies the clue—social circumstances, for instance, a recent injury, a dangerous occupation, or exposure to infection—is often more difficult to ascertain. (On the whole we know more about disturbances of function than about pathological processes.) Moreover, the same disorder of function may be due to many different pathological processes with the result that accurate diagnosis of the functional disturbances in a patient does not necessarily help in the diagnosis of their underlying cause. Nevertheless, certain guiding principles stand out, and, in order to complete the picture which I am endeavouring to paint, let me state them briefly.

Symptoms which a patient refers to his mind can originate in mind or body, but, amnesia excepted, are seldom deliberately invented. (Physical symptoms serve the malingerer better.) Anxiety, inability to concentrate, and mental fatigue are usually psychoneurotic, severe emotional disorders psychotic. Confusion and intellectual impairment are usually organic, delusions and hallucinations, when consciousness is clear, psychotic.

Symptoms which a patient refers to his body can also originate either in his body or in his mind. Fantastic symptoms—fantastic in the sense that they cannot be explained in terms of any known disturbance of function—must be invented by the mind, even pain must be hysterical when it lacks the features of true pain, and is probably hysterical, in part at least, if it is clearly serving the patient's purpose. Possible symptoms—that is to say, symptoms capable of functional interpretation—when unrelated to demand on function are probably psychogenic, if of the visceral variety, due to anxiety stimulating overaction of the sympathetic, if of the somatic variety, due to the mind intervening subconsciously in the affairs of the body through the skeletal motor nervous system. Physical symptoms related to functional demand which have remained unchanged for long periods, or supervened only with increased demand on function, are probably due to excessive demand on function weak for genetic or acquired reasons. As we all know, it is the new symptom related to normal demand on function, in a patient who has never had any weakness in that direction previously, which suggests organic disease.

But from time to time organic disease starts in the neurotic person, and then the interpretation of symptoms is particularly liable to go astray unless physical signs are discovered to keep the diagnosis straight. For the absence of physical signs does not exclude organic disease, or their presence necessarily indicate that it exists. All signs are not of equal significance. Some can be due to excessive demand on normal function or emotion interfering with the functions of the body, and to organic disease. Others cannot be produced either by emotion or excessive demand on normal function, and can only be due to conscious or subconscious intervention of the mind in the affairs of the body or to direct action on the body. Distinction within this group is, however, seldom

difficult. Signs which conform to anatomical fact and physiological law must be organic, signs which fail in this respect can only be explained in terms of processes of mind. A third group can only be produced by a pathological process of the body, their nature ruling out all other possibilities. A large heart must be due to dilatation, a consequence of organic disease, or to hypertrophy, a reaction to increased demand on function. No emotional stimulation or subconscious intervention of the mind in the affairs of the body can paralyse a single muscle or diminish the entry of air into one lung. Mind can influence structure, but the power of the mind does not extend as far as that. Provided signs of this kind are certain, the patient must be suffering from organic disease even if his other signs are all of psychogenic origin. Hence the pride of place of certain physical signs, and the importance, as we all know, of the routine examination of every patient.

Nevertheless, even when no abnormal physical signs can be found, impressions gained from the history often add up with unexpected accuracy, to suggest that a patient's symptoms are due either to an excessive demand on normal function, to an organic pathological process interfering with his body or his mind, to a psychosomatic condition, or to a psychoneurotic reaction of his mind interfering with the functions of his normal body. Moreover, when he is clearly suffering from some organic condition, the combination of functional disturbances and structural changes in relation to his age and the length of his history is often sufficiently characteristic to suggest that a congenital defect, malnutrition, injury, chemical poisoning, new growth, or the degenerative processes of advancing age (it is often worth while to go through the list systematically) is the cause of the symptoms of which he came complaining.

A clinical diagnosis in this sense—a diagnosis based on the history, in so far as it can be obtained, and a physical examination, carried out as completely as circumstances permit—that is to say, a diagnosis on the evidence immediately available, is, I would have thought, necessary in every single case. Whether an X-ray examination or laboratory tests are required to confirm or extend it, or exclude some dangerous although less likely condition, is often a very difficult decision, and must depend, it seems to me, on an assessment of the chance of being right on clinical evidence alone, and on the chance of any condition from which the patient might be suffering being amenable to treatment. In fact it depends on an estimate of probability.

Initial diagnosis, on which so much depends, therefore can seldom be scientifically exact (as administrators of medicine sometimes forget), and for this reason there is a natural tendency today to make more and more use of the many investigations which can now be called upon to help in the diagnosis of a difficult, or paint the picture more completely of an interesting, case. Moreover, these are steadily increasing in number and complexity, and we can now shelter behind them in almost every case if we feel disposed, particularly as patients are increasingly tending to demand them themselves instead of relying on our clinical judgment. But we cannot afford to be too extravagant and a halt in their use sometimes must be called. One thing is certain. Clinical diagnosis should always go before and laboratory investigations follow after. (In the midst there must often be much hard thinking.) If the order of the procession is reversed investigations tend to pile up and the management of a case may go seriously astray. Besides, we must be prepared to take some risk, after exercising all reasonable care, and even refuse investigations sometimes when they are demanded by patients, or practical medicine will soon become impracticable. When a patient is clearly beyond human help an accurate diagnosis is likely to be quite irrelevant to

treatment and, therefore, investigations correspondingly unnecessary. Moreover, they should not be carried out merely as a shield against criticism, seldom ordered for our own interest alone, and except for research purposes seldom considered, particularly in old people, unless likely to yield results on which therapeutic action might be taken. Only if we adopt a definite policy on these lines shall we keep their charge on recurrent expenditure from rising (leaving more money for capital development) and reduce the unnecessary discomfort which they cause and the unnecessary anxiety which they often engender in the minds of our more sensitive patients.

The investigations sometimes necessary to confirm or supplement a clinical diagnosis are of four kinds. Some reveal new subjective symptoms or create new objective signs. The injection of cold water against the tympanic membrane leads to vertigo and nystagmus when the semicircular canals are functioning normally. Others describe subjective sensations or objective signs with greater accuracy than ordinary demands on function, or the tests to which the patient subjects himself, readily permit. For instance, vision is tested by reading Snellen types and hearing by sounding notes of different frequency with increasing intensity. The perimeter maps out a defect in the visual fields, and the audiometer measures the reduction in his range of hearing which the patient had only vaguely noticed himself. A third group extends the ordinary clinical examination of the patient by means of three of our senses, vision, touch, and hearing. Inspection of the shadows cast by tissues in the path of electromagnetic radiation, and looking inside the body by means of tubes, mirrors, and lenses, do not differ fundamentally from the ordinary inspection of the patient. The polygraph records the pulsation in the radial artery which the finger can, and that in the jugular vein which the finger cannot, detect and translates them into a permanent record. An electrophonograph amplifies heart sounds. A fourth group records changes in the physicochemical machinery of the body which are not directly reflected in the subjective sensations or objective signs, a knowledge of which is often necessary for the fuller understanding of disease. Chemical analysis of the body fluids throws light on metabolic disorders. Immunological technique studies antigen-antibody structure which as yet defies analysis at the chemical level. The string galvanometer records the electrical concomitants of physicochemical changes in the heart and nervous system.

Treatment of the Patient

But there may be no time for investigations. An acute disturbance of bodily function may dominate the situation and demand immediate action on a clinical diagnosis. In another case an acute reaction of the mind has created a scene and order must be restored. In a third case symptoms point to a functional disturbance trivial in itself but pointing in its turn to a pathological process rapidly heading towards disaster, and which must be immediately arrested. More often symptoms point to some disturbance of function which must be relieved while investigations are in progress, or to a reaction of mind which cannot long be ignored, behind which lies some pathological process, which might perhaps have been prevented, and which cannot now be safely left to run its course. These three aspects of treatment make up the art of healing.

The functional balance of the body must be maintained, as far as possible. Demand on failing function should be reduced, but vital functions must, like His Majesty's Government, be carried on at basic level. The respiratory centre or the heart may demand stimulation with drugs, in a long illness enough food must be given to maintain nutrition, and in a short one enough fluid

to maintain hydration and ensure renal secretion. When function fails altogether it can sometimes be operated artificially. Thus the lungs can be ventilated mechanically, a skeletal muscle stimulated electrically, and endocrine function maintained chemically. Substances lost from the body—corpuscles, plasma salt, water—can be restored. Failing function can often also be relieved by plastic operations, as in the treatment of some congenital defects, transplantation of tendons in long standing paralysis, and fixation of joints in chronic arthritis. In many cases the treatment of failure of a function coincides with the treatment of the pathological process. Thus excision of the lens lets light into the eye, and removal of the prostate urine out of the bladder.

On the other hand function out of proportion to the needs of the body must be curtailed. The activity of a gland can be reduced by ligation of some of its vessels, removal of part of its substance, division of its nerve-supply, or the administration of drugs. Alternatively its secretion can be neutralised chemically or countered pharmacologically. Spasm of plain muscle can be relieved by stimulating sympathetic or inhibiting parasympathetic nerve endings. Hyperpyrexia can be controlled by promoting evaporation, and an unproductive cough relieved by drugs which depress the respiratory centre. The rapid division of cellular tissue can be inhibited by radiation. Pain, irritation, and sleeplessness can be relieved by hypnosis and by drugs. Pain can often be relieved without drugs if the mechanism of its production is understood, for instance, by minimising demand on function, preventing movement, reducing congestion, and relieving tension. Severe pain can sometimes be relieved by blocking pathways in the nervous system, temporarily by means of drugs, permanently by their division with the knife and by the operation of leucotomy.

Meanwhile the conscious reactions of the patient's mind can seldom be ignored. Every patient reacts to the pain, discomfort, anxiety, and curtailment of his life which result from his disease. Normal reactions demand sympathy and understanding, but the patient who reacts too little must be frightened into taking more, and the patient who reacts too much encouraged to take less, care of his physical health. Psychotherapy, which the psychoneurotic reactions demand, depends on the influence which one mind can exert directly on another through the ordinary channels of communication between them, and demands a natural capacity for sympathetic understanding of another person's problems which can be bred out of existence by an unbalanced scientific training. It relies mainly on persuasion, suggestion and reason, based on an appeal to self-interest or, when self-interest and social duty conflict, to accepted moral standards. Psychoanalysis goes further and attempts to unravel the past development of the individual mind in relation to emotional reactions to experience, which contribute to the development of personality, and release repressed emotion which is causing mental tension. The patient is compelled to live through his emotional experience again, and learn the cause of his previous fears and obsessions so that he will be able to adapt himself more satisfactorily in the future to circumstances outside his control. The reactions of the mind can also be modified through the physiology of the underlying brain. Some drugs detach the mind from reality, others release inhibition. Many depress the higher functions of the nervous system and can be used to rest the mind. A few reduce reaction times raising the efficiency of the mind for a while a little above its average level, and are of some value in the treatment of depression.

But psychotherapy may cut no ice. Treatment of a functional disturbance of the body, attention to general health, or alteration of environment alone may be of

little avail. There may be no known pathological process active in the body. Under these circumstances treatment must attempt to alter the psychosomatic constitution of the patient (which in some way has rendered his body liable to succumb more easily to emotional stimulation or his mind to physical ill health), and must be directed to mind and body simultaneously in proportion to the part which each is playing in the individual case, the intensity of treatment depending on the degree to which his personality has changed already or was at fault from the beginning. True, human experience suggests that inward conviction may result in a revolution of human personality subsequently reflected in alteration of constitution of body, but dramatic changes of this type, however they are produced, transcend our ordinary methods of psychotherapy, and we are compelled either to resort to empirical treatments directed to the brain on which the mind is based, or to attempt to alter the endocrine pattern of the body on which the brain depends.

Convulsions induced by chemical substances or by electrical stimulation of the motor cortex seem to be of some value in depression, and insulin hypoglycæmia to be of some use in schizophrenia. Prefrontal leucotomy dissociates the emotional from the intellectual reactions of the mind, and will often reduce an agitated, depressed, or excited patient to a socially more manageable state, but usually at the expense of some deterioration in his personality. The same operation, the results of which are always difficult to predict, is also said to abolish mental symptoms in severe anxiety states, although it often leaves the associated physical symptoms unchanged. We must wait to see to what extent (if any) structural changes in the body, such as simple ulcer, and functional disturbances, such as high blood-pressure, will respond to personality change produced by operations on the brain.

Alternatively we can attempt to alter the endocrine pattern of the body which is well known to have influence on the reactions of the mind. Thyroid will certainly restore the intelligence in myxœdema, and some of the mental symptoms of thyrotoxicosis respond to thyroidectomy and thioracil. The sex hormones are known to relieve the physical and mental symptoms associated with the constitutional change through which women pass at the menopause, and are of some value in restoring normal secondary sexual characteristics and normal instinctive reactions in people suffering from deficiency of the internal secretion of their reproductive glands, although they will not convert a homosexual into a heterosexual person or influence instinct appreciably when the endocrine system is normally balanced. (Reactions of the latter kind are at a higher level of development of personality.) But the recent discovery that an extract of the suprarenal cortex will relieve the symptoms of many of the rheumatic diseases, suggesting that some people are predisposed to succumb to adverse factors in environment by the peculiar endocrine balance of their body raises altogether new possibilities. Further, the fact that 'Cortisone' may have a profound effect on the reactions of the normal mind suggests that we may acquire the power to relieve physical diseases of certain kinds by means of related substances, only at the expense sometimes of altering the patient's psychosomatic constitution in such a way that he reacts differently to experience in future. On analogy with drugs, any change of personality produced is likely to be for the worse rather than for the better. That is all that can be said. I think, at present.

Genetic disease could be prevented to some extent by the eugenic control of marriage if that was practicable, but the compulsory sterilisation of the genetically unfit would be unlikely to prove very effective, because of the pool of recessive genes latent in the general

population. It is sometimes possible, however, to remedy a genetic defect as in a plastic operation for hereditary cleft palate or in splenectomy in familial acholuric jaundice. A hæmolytic reaction in a newborn child can be treated by transfusion with Rh negative blood, but damage to the fixed tissues cannot be undone, and it is difficult to see how risks of this kind are to be prevented. But it is possible to control to some extent the internal environment which the potential mother provides for her developing child and prevent some of the other diseases which can be acquired at birth during intra uterine development. Every pregnant woman can be Wassermann tested, and should avoid the risk of infection, particularly virus infection, during the first three months of pregnancy. Antenatal supervision ensures the diet which foetal growth demands, reduces the risk of severe toxæmia, and anticipates obstetric complications.

I can refer only very briefly, in order to complete my picture, to the prevention and treatment of disease due to pathological processes apparently acquired during life. The risk of accidents and chemical poisoning can be reduced by legislation, and the prevention of malnutrition is a problem of social administration and individual education. Infective disease can be prevented to some extent, sometimes by reducing the risk of exposure to infection, as in tuberculosis, sometimes by raising natural resistance, as in inoculation against typhoid, sometimes by reinforcing the natural defences of the body, as in passive immunisation against diphtheria, and sometimes by maintaining a sufficient concentration of antibiotic in the blood, as in the prophylaxis of malaria. Established infection can sometimes be overcome by reinforcing the body with preformed antitoxin, but far more often far more successfully by so altering the internal environment of the patient with chemotherapeutic or antibiotic substances that pathogenic organisms cannot continue to live and multiply in his body. Nevertheless, in spite of spectacular advances in therapeutics in this direction recently, surgical excision is still the treatment of choice in some chronic infections, and in most varieties of malignant disease, unless the necessary operation is too mutilating or the risk entailed to life too great. Radiation is the best treatment for a few types, and will relieve pain and slow the progress of the disease in inoperable cases. Stilbæstrol will inhibit the progress of carcinoma of the prostate. But the world still waits for a chemotherapy for cancer. It is not impossible. Let us hope, however, that science will never discover any method for slowing down, in the fullness of their time, the otherwise inevitable degenerative changes of advancing age.

The Practice of Medicine

As medicine advances, our responsibility increases. There can be no escape from that conclusion. It is already difficult to decide when and how many new treatments should be used. For, unlike mechanical engineers or commercial chemists, we are seldom faced with clear cut material problems as teachers, ignorant of the real nature of medical practice, sometimes suppose. Many other considerations have to be taken into account, and again and again we have to take risks, for to a large extent we are often working in the dark. Moreover, medical practice deals in a peculiarly intimate way with people in distress and with the hopes and fears of individual finite lives. It demands, therefore, insight, personality, and understanding. It is true that more scientific knowledge may be necessary as medicine becomes technically more difficult, and that critical ability and intellectual honesty, not a monopoly of the scientific mind, are required more than ever before. But medicine must often reckon with abstract values of which science by the nature of its method cannot,

and with moral problems of which science by the nature of its matter need not, take account. Medicine cannot altogether evade the question of what the individual man should be. I sometimes think that the unbalanced scientific training which our universities provide is an inadequate education for a man or woman destined to spend his or her life in the practice of the art of medicine.

The prevention of disease on a large scale in many parts of the world is rapidly leading to increases in population which must inevitably result in famine unless food supplies are soon increased or the voluntary restriction of births, which is contrary to nature, comes into operation sufficiently soon to prevent disaster, which is distasteful to human sentiment. But problems of this kind lie outside our individual control possibly largely outside human control. We, as doctors, are mainly concerned with the individual man, woman, or child, with one individual problem after another, and the general practitioner, among other problems of this kind, with the prevention of disease in his potential patient. He must make up his mind as to the extent to which it is worth trying to prevent it before it starts, or diagnose it before it has passed the stage at which it can be treated, by encouraging over careful living at the expense of loss of morale, or by insisting on repeated investigations at a considerable cost to the State. He too must decide when to advise birth control on account of poverty or housing difficulties, and the circumstances under which the termination of a pregnancy is justifiable. He is confronted with many problems which he little thought of in his student days. To what extent is it reasonable to relieve pain, or to allow a patient to avoid work, or gain this or that privilege, when things are short, on a medical certificate? To what extent should he help a person to avoid punishment on the strength of medical evidence? When should he approve an operation on the brain to solve the social problem created by a disorder of the mind or use endocrine preparations, as may be possible in the future—medicine being in a rapidly progressive, experimental, and correspondingly dangerous phase—to relieve physical symptoms, at the price of some deterioration in his patient's personality? When should he allow a man to refuse the operation which might save his life now that surgery has become so safe? When should he advise an operation merely to prolong life when by all ordinary standards his patient's life has long since ceased to be worth living? When, by deliberate non intervention, is he justified in letting his ageing patient depart this life in peace?

Unfortunately recent advances in medicine, which have precipitated or aggravated so many of these problems, have led to a loss of confidence all round the doctor in his capacity to deal with many of his patients, the patient even in the doctor of his choice, the State in the doctor, and the doctor in the State. Hence, the flight from the general practitioner to the specialist who sees his patient divorced from his natural environment, the pregnant woman in the antenatal clinic away from her husband, the infant in a welfare centre away from its home, the child in school away from its parents, the man at work away from his wife, or the suspected case of this or that in his special clinic. What opportunity has he to size up the situation as it affects an individual private life? And yet the biological characteristics of man are such that the family must remain his unit of society. Far too often, I think, are they forgotten. Children are dependent on their parents well into their 'teens, the next child normally arriving when the last is still at nursery age. Boys and girls reach sexual maturity many years before they reach physical maturity, marriage being delayed by universal consent in civilised countries. Men and women live for years, and often do their best work, long after

active sexual life is over, and eventually become dependent on their children as their children once depended on them. These are statements of fact, differences between the animals and man. Human health, particularly health of mind, depends to a large extent on the maintenance of family life, one of the privileges of the human race which modern economic conditions, easy divorce, and communist theory—the last two, it seems to me, based on sentiment rather than biology—are tending to disrupt. Unfortunately the influence of the family doctor is slowly waning as the structure of society is changing at a time when we have no agreed philosophy of life.

* * *

In these two lectures I have endeavoured to outline a concept of medicine as a single undivided whole such as an ordinary mind can grasp and on which we might all to some extent agree. I have therefore described, as I see it, the nature of disease, about which we still know little, the nature of the patient, about which we know less, and the nature of the practice of medicine which grows more difficult I sometimes think, almost every day.

Nevertheless, the power of medicine over human minds and human bodies "has increased, is increasing, and is likely to increase still further." I do not suggest that this power should be reduced, as Dunning once moved in the House of Commons of the increasing power of the Crown. But I do venture to remind you that there is danger in power. There is always danger in power, particularly in power acquired before we have decided how it should be wielded, as the release of atomic energy has recently revealed. Safety in the face of coming advances in biophysics and biochemistry seems to me to lie only in the freedom of the patient to choose his own doctor, and in the freedom of the doctor to choose his own treatment. Moreover the family doctor, properly trained, guided by specialist advice, and knowing all the circumstances of the individual life, should be the person mainly responsible for deciding when the increasing power of modern medicine should be used, in spite of the increasing responsibility which moral decisions of that magnitude entail.

There are difficult problems but of one thing I am absolutely certain. Medicine must be organised centrally, but until we reach an agreed philosophy of life, and that prospect seems infinitely remote, I am convinced—I here venture to claim to speak above the political level—that the nature of the patient is such, and that the nature of his or her disease is such, and that the nature of medical practice is such, that under no circumstances, and in no country, and at no time should the growing power of medicine ever be handed over unfettered to the State.

The use of the term psychosomatic medicine, as if it were something new, has become widespread in this country. In terms of research psychosomatic medicine may justifiably be considered an independent discipline but regarding treatment of patients it is hardly more than good medicine with equal consideration of all factors involving the patient—physical, emotional and environmental—and with the special therapeutic skill of the psychiatrist called upon when indicated. The somewhat confused emphasis on psychosomatic medicine in this country may be partly a result of the isolation of the hospital patient from the physician who really knows him from taking care of numerous minor ailments and who knows his failings and his vagaries through knowledge of his family setting and as a member of a community. However the psychosomatic point of view in medicine or in other words consideration of the patient as a whole is one of the essential attributes of the family physician.—J. A. UNIVERSITY OF CAMBRIDGE

In the course of investigations on the use of the anti globulin test for detecting red cells sensitised with human antibody, van Loghem et al (1950) observed that the cells from three cases of acquired hæmolytic anaemia were negative when tested with low dilutions of some anti globulin sera. When cells from these patients were tested with more dilute samples of the same anti globulin sera, however, a positive result was obtained.

This prozone effect is shown in table I (taken from van Loghem et al. 1950).

On further testing various dilutions of one of these anti globulin sera (no 132) against Rh positive cells sensitised with various dilutions of incomplete anti D antibody, it was observed that the prozone effect depended on the concentration of the sensitising antibody (anti-D) as well as on the concentration of the anti globulin serum used (table II). The diluent for these tube tests was normal rabbit serum, diluted 1 in 20, from which agglutinins against human cells had been absorbed. When saline was used as a diluent, the reading of agglutination with the microscope in those tubes containing highly diluted serum was difficult and untrustworthy.

An example is also given in table II of a powerful anti globulin serum, no 1914, which did not exhibit the prozone phenomenon. It was thus felt that further investigation into the cause of this prozone effect would be of interest.

Two possible explanations suggested themselves:

(1) That the anti globulin sera contained not only powerful agglutinins operating to a titre of about 1:500,000 but also an 'incomplete form' of anti globulin antibody of a much

Fig 1—Parts of two red cells each carrying an incomplete anti D molecule. An incomplete form of anti-globulin antibody is attached to each globulin receptor preventing agglutination from combining. Both forms of anti-globulin antibody are in excess.

Fig 2—Each Rh antibody globulin receptor is occupied by a molecule of anti-globulin antibody and so agglutination does not take place. Anti-globulin is in excess.

The figures are designed to represent as accurately as possible the serological properties of the reagents and have no other significance.

lower titre. It might be postulated that the incomplete antibody was more avid than the agglutinin and, in combining preferentially with the globulin receptors on the sensitised cells, blocked them against the action of the agglutinin (see fig. 1). In the higher dilutions, however, only the agglutinin would be effective.

(2) The second explanation was that the phenomenon was an inhibition due merely to antibody excess, such as is encountered in certain precipitation systems. This explanation is represented in fig. 2.

This latter hypothesis, however, does not necessarily exclude the presence of "incomplete forms" of anti-globulin antibody which may fail to exert a significant blocking effect. The hypothesis merely lays the responsibility of the causation of the prozone on the excess of the "agglutinating" antibody, whether or not an "incomplete form" is present in the serum. Furthermore, this hypothesis does not exclude the possibility that in some anti globulin sera a "blocking form" of antibody may be present and cause an inhibition zone over a

range similar to that observed here. Though the two theories are not mutually exclusive, the evidence which we present in the following experiments favours the second.

EXPERIMENT I

A 3% suspension of red cells group O, cDE/cde was allowed to react with an equal volume of incomplete anti-D antiserum (diluted 1:200) for 20 minutes at 37°C. These sensitised cells were then washed four times in saline and, some being set aside, allowed to react for a further 20 minutes at 37°C with an equal volume of

an equal volume of anti globulin serum in a dilution falling in the inhibition zone (one in three). These cells were then rapidly washed three times in saline, and two separate volumes were placed on a clean white glass tile. To one volume was added an equal volume of cells sensitised only with incomplete anti D (cells set aside as above), and to the other part washed unsensitised cells were added. The results, read after 3 minutes, are given in table III.

It will be noticed that after the sensitised cells, which had been saturated with anti globulin antibody, had been washed, the supernatant fluids, both from the last washing and from the test cell suspension, were tested against cells sensitised with incomplete anti D, to demonstrate that no free or dissociated anti globulin antibody remained. The experiment has been repeated several times both in Amsterdam and at Cambridge independently with the same result.

Fig 3—Left upper figure shows part of a sensitised cell that has adsorbed anti-globulin and has been washed right upper figure shows washed sensitised cell Agglutination takes place in these circumstances Lower part of figure represents control experiment in which unsensitised cells are added no agglutination takes place

[illegible]

Discussion

This result supports the hypothesis that excess of antibody may be the cause of the inhibition, as illustrated in fig 3. If the test cells are saturated with an anti-globulin agglutinating antibody, it is likely that agglutination would be brought about by the addition of more antigen combining groups. It must be remembered that in this system the antigen combining groups are probably molecules of antibody globulin attached to the cells, and therefore, to furnish more antigen groups, it is necessary merely to add sensitised cells, as in this experiment, this step caused the cells to agglutinate powerfully. The addition of normal unsensitised cells provides no new antigen receptors, and no agglutination would be expected, in fact, no agglutination was observed. It can be seen that the validity of these deductions depends on the thorough washing of the cells at each stage.

It is evident that the result of this experiment does not favour the hypothesis of an "incomplete form" of

anti globulin antibody as the cause of the prozone effect, for the addition of sensitised cells would be unlikely to influence the properties of the cells saturated with a "blocking form" of incomplete anti globulin antibody (see fig 4).

EXPERIMENT II

A further attempt was made to strengthen the view that excess of antibody was the cause of the inhibition. Cells prepared as in experiment I (sensitised with incomplete anti D and subsequently with anti globulin in the inhibition zone and washed thereafter) were added on a tile to a series of dilutions of 2½% human γ globulin (Cohn fraction). After preliminary experiments suitable dilutions of globulin were found. The results, read at 3 minutes, are given in table IV. Further controls for this experiment are discussed later.

Discussion

If the sensitised cells were saturated with an anti-globulin agglutinating antibody, it could be argued that very small quantities of globulin might combine with the free "valencies" on two or more cells and so cause agglutination (see fig 5). In these circumstances, in fact, very strong agglutination took place. A large quantity of globulin, however, would merely saturate all the available combining sites without causing agglutination (see fig 6). It is difficult to see how this result could be adduced in support of an "incomplete form" of anti globulin causing inhibition through blocking. If, on the one hand, the "incomplete forms" of antibody fail to bring about agglutination by being univalent, it would not be expected that the addition of globulin to the test complex would so alter this univalent property as to cause agglutination. If, on the other hand, the agglutination of sensitised cells is less an expression of the properties of the antibody and rather an effect of the medium in which the test is conducted—e.g., albumin, or other serum-proteins—it could not be argued that the addition of a 1 in 100,000 dilution of 2½% γ globulin would so alter the environmental conditions

TABLE IV—THE AGGLUTINATION OF RED CELLS, SENSITISED WITH INCOMPLETE ANTI D SERUM AND WITH ANTI-GLOBULIN SERUM IN THE INHIBITION ZONE AND SUBSEQUENTLY WASHED BY HUMAN γ GLOBULIN

physically as to bring about agglutination. Indeed, this concentration of globulin does not cause agglutination when added to cells strongly sensitised with incomplete anti D. We therefore regard this experiment as additional support to the hypothesis that the inhibition phenomenon is due to excess of antibody rather than to a "blocking form" of antibody.

OBSERVATIONS ON TECHNIQUE

The experiments described have been repeated several times with unequivocal results. However, during the

early stages of this work the controls on several occasions showed very weak agglutination, particularly when the experiments were conducted in tubes. This irregularity necessitated further experimental investigation into the controls of the reagents employed. These experiments are not described, but it was felt that some of the conclusions drawn from this work should be mentioned for the assistance of those who may wish to use this system for further investigations. Certain optimal conditions were found to be desirable. The red-cell suspension gives the best results at a concentration of not less than 3%. To obtain good inhibition it is desirable not only to use the anti globulin serum at a dilution well within the prozone but also to sensitise the cells with the weakest dilution of incomplete anti D that will furnish a strong agglutination in the presence of the optimal concentration of anti globulin. The anti globulin sera had been heated to 56°C for 30 minutes.

Perhaps the most important observation made was the necessity for thoroughly washing at the start the red

Fig 4—Sensitized cells on left have adsorbed an incomplete form of anti-globulin and have been washed. The addition of washed sensitized cells (upper right) would not be expected to cause agglutination (cf fig 3).

Fig 5—Molecule of human γ -globulin can unite with anti-globulin adsorbed on to sensitized cells and agglutination results.

Fig 6—Excess of globulin. Combining sites are saturated and agglutination does not take place

cells to be used for the normal cell control. It was shown that at least four washings were necessary. If the cells were washed twice or three times, a trace of serum globulin remained in association with the cell suspension and brought about weak agglutination of the sensitised cells saturated with anti globulin antibody. The mechanism of this weak agglutination is thus the same as that shown in experiment II. When the cells were washed four, five, six, or seven times, this effect was not observed. The cells after sensitisation with incomplete anti D must likewise be washed four times for the same reason.

When the sensitised cells are saturated with anti-globulin antibody, the possibility of dissociation of the anti globulin antibody from the cells required consideration. This might happen spontaneously over a period of time on standing, or as a result of centrifuging. Such dissociation might lead to the spontaneous agglutination of these cells. For this reason we preferred to perform our experiments on a tile, where the results might be read after 3 minutes, rather than risk the delay involved at this stage by a tube test. The fact that the sensitised cells, saturated with anti globulin antibody and washed four times, were still unagglutinated after 10 minutes on a tile (whether or not a volume of saline was added) showed that dissociation was not complicating our results.

CONCLUSIONS

It has been found that some anti human globulin sera, when tested against red cells weakly sensitised with human globulin, exhibit a prozone. The clinical significance of this observation is that, by employing such an anti-globulin serum diagnostically, falsely negative results may be obtained. To overcome this difficulty it is necessary to examine the anti globulin sera in routine diagnostic use to detect whether such a prozone is present. This step consists merely in titrating the anti globulin serum against cells weakly sensitised with incomplete anti D. It should be remembered that the anti globulin sera should have been thoroughly absorbed with washed human cells, for weak heterogenous agglutinins against human cells might mask the presence of a prozone. Any anti globulin serum showing a significant prozone should be rejected from routine diagnostic use, for it cannot be maintained on the evidence available at present that an "optimal dilution" of an anti globulin serum as determined on one sample of sensitised cells will necessarily be optimal on another.

Possibly only a few anti globulin sera will exhibit this prozone phenomenon. The experiments detailed here are based on one serum showing a powerful prozone, and van Loghem et al (1950) describe three others. However, it can be seen from table II that a powerful anti-globulin serum without any prozone effect may readily be obtained. The table also illustrates that even anti globulin sera of this kind must be carefully assessed before use. If our anti globulin serum no 1914 were titrated against strongly sensitised cells to determine the agglutinating dose, it would be necessary to use the

serum at a strength of 128 agglutinating doses to detect weakly sensitised cells effectively. The strength of anti globulin sera should therefore be investigated thoroughly, so that they may be used at a dilution which will detect weakly sensitised cells.

The serological significances are twofold. First, our experiments support the hypothesis that the prozone effect observed with this serum was due to inhibition by excess of antibody. It does not seem possible to explain these results on the assumption that this inhibition was caused by a "blocking form" of incomplete anti globulin antibody. However, it would not be denied that "incomplete forms" of antibody might be encountered in other anti globulin sera, nor that they might cause a prozone effect. Indeed, our observations and other experiments not reported here demonstrate several unexplained properties of anti globulin sera which are now being investigated. This paper is concerned solely with the cause of the prozone phenomenon encountered in one anti globulin serum.

Secondly, it seems possible that the experimental results may be adduced as evidence in favour of the multivalence of antibodies, at any rate of the anti globulin antibody. The term multivalence is here used to include bivalence; it does not seem possible or significant for the present argument to distinguish between bivalence and multivalence. We therefore use only two alternative terms, univalence and multivalence.

These experiments seem to demonstrate that, when sensitised cells are saturated with anti globulin antibody, one valency is at this stage occupied by union with the globulin combining unit attached to the red cell. This complex may then be thoroughly washed free from all other materials, and then, by the sole addition of a suitable concentration of γ globulin, agglutination can be brought about. The reaction at this second stage seems to indicate that one or more hitherto unsatisfied valencies are brought into combination with antigen. In summary, it appears that one valency of the antibody may be occupied at one stage of the experiment and, after all other material has been washed away, a second valency or more valencies may be satisfied at another stage, judged by the visible result of agglutination.

We wish to thank Mr H P Hudson and Mr C Patman for photographing the diagrams.

GAMMA GLOBULIN IN THE PREVENTION AND ATTENUATION OF MEASLES CONTROLLED TRIALS IN DAY AND RESIDENTIAL NURSERIES*

A REPORT TO THE MEDICAL RESEARCH COUNCIL

The gamma globulin fraction of normal human plasma, prepared by the method of Cohn and his associates (1944), has been shown by Stokes et al (1944), Ordman et al (1944), Greenberg et al (1944), and a subcommittee of the Medical Research Council (1948) to be a safe and effective agent for the passive immunisation of

* The trials were carried out on behalf of the Gamma Globulin Conference of the Medical Research Council (chairman, Sir ALAN DRURY, F.R.S.) by Dr W C COCKBURN and Dr J A HARRINGTON of the Central Public Health Laboratory in collaboration with medical officers of health of municipal boroughs in the county of Middlesex and Sir Allan Daley, F.R.C.P. and the staff in charge of the L.C.C. nurseries, Dr T ANDERSON, Knightswood Hospital, Glasgow, Dr MARGARET SPROUL, senior maternity and child welfare officer, Salford, Dr B J GRIFFITHS, assistant medical officer of health, Manchester, Dr A M-M PAYNE of the Public Health Laboratory Service, Oxford, Dr A B SEMPLE, deputy medical officer of health, Liverpool, and others.

susceptible measles contacts, and to be more potent and less likely to give rise to untoward reactions than agents previously used.

At the Lister Institute of Preventive Medicine, Kekwick and Mackay (1949) developed a method for the preparation of gamma globulin in which the precipitating agent was ether instead of the ethanol used in Cohn's procedure. In 1947-48 a small amount of crude globulin prepared by the ether method was made available for controlled studies in susceptible measles contacts. About 50% of the total protein in this crude globulin was gamma globulin. Some was supplied as a liquid, and some was freeze-dried in separate doses for reconstitution immediately before use. Preliminary studies were carried out mainly in children in day and residential nurseries during a measles epidemic, and, though the numbers were small, the modification in the severity of the illness was found to be substantially greater in children given globulin than in those given adult serum. In view of these findings and the absence of untoward sequelæ a large-scale investigation was organised in day and residential nurseries in preparation for the expected rise in the incidence of measles in the early months of 1949.

DETAILS OF INVESTIGATION

Globulin

The material used in most of the 1949 trials was freeze-dried in doses containing 250 mg of protein, of

TABLE I—COMPOSITION OF TRIALS, SHOWING NUMBER OF NURSERIES IN WHICH MEASLES DEVELOPED WITHIN 21 DAYS OF INOCULATION OF CONTACTS

	London		Provinces		All areas

which 90-95% was gamma globulin, but in six trials a dose containing 500 mg of protein was given. Each dose was dissolved in 3 or 6 ml. of sterile distilled water immediately before injection.

Plan of Inquiry

To assess the value of gamma globulin it was necessary to compare the experience of the children given gamma globulin with a similar group of children not so treated, and it was decided to inoculate half the children with 5 ml. of adult serum or reconstituted dried plasma, which previous experience had shown would slightly modify the disease without apparently influencing the attack-rate. (For convenience, both adult serum containing 0.5% phenol and reconstituted dried plasma will hereafter be called "adult serum".)

In each trial centre, medical officers in charge of the investigation made a preliminary visit to the nurseries and explained the details to the matrons and staff, particularly emphasising the need for immediate notice of the first definite or suspected case of measles among the children. With the co-operation of matrons it was possible in all instances to inoculate the presumed susceptible contacts within seven or two hours of the appearance of the rash in the primary case.

On being notified of the first case in one of the nurseries in his area the medical officer visited the patient or satisfied himself of the accuracy of the diagnosis by

TABLE II—AGE AND SEX DISTRIBUTION OF CHILDREN IN THOSE SECTIONS OF NURSERIES WHERE MEASLES DEVELOPED WITHIN 21 DAYS OF INOCULATION

Age-group (months)	Children on adult serum			Children on gamma globulin		
	Male	Female	Total	Male	Female	Total
6-11	2	6	8	7	3	10
12-17	35	37	72	44	32	76
18-24	44	35	79	32	40	72
25-35	17	13	30	19	15	34

reference to the practitioner concerned. He then made a list of all the susceptible nursery contacts whose parents had consented to inoculation, dividing them into subgroups according to the intimacy of exposure (previously defined for the purpose), with the children in each subgroup in order of increasing age. The names on these lists were then divided into pairs, so the paired children were closely similar in intimacy of exposure and age. One of each pair was inoculated intramuscularly with gamma globulin and the other with adult serum, the choice being decided from lists supplied by Prof. A. Bradford Hill, D.Sc., of the Department of Medical Statistics, London School of Hygiene and Tropical Medicine. Prof. Bradford Hill, who also gave much other advice on the planning of the investigation, provided for each area a series consisting of pairs of letters—"G" for gamma globulin and "A" for adult serum—the order in which they appeared in a pair (GA or AG) having been determined by random sampling numbers. Each pair of letters was used once only and then crossed off the list. Thus two similar but randomly constructed groups of children were obtained.

Since it was desirable that the severity of cases should be assessed without the observer knowing which children were in which inoculation group, the details of the inoculum given were noted on a record sheet which was filed away as soon as the inoculations in each nursery were completed, and subsequent clinical observations were recorded on a separate record sheet, the preliminary investigation had shown that it was practically impossible for the observer to remember after inoculating the children whether a particular child had been given gamma globulin or adult serum.

The inoculated children were kept under observation for twenty-one days, and those in day nurseries were visited in their homes during this period if they were absent from the nursery. If none of the contacts developed measles within twenty-one days of inoculation, the trial was closed.

TABLE III—DEGREES OF EXPOSURE IN GLOBULIN AND ADULT-SERUM GROUPS IN NURSERIES WHERE MEASLES DEVELOPED WITHIN 21 DAYS OF INOCULATION

Nature of contact with primary case	Children on adult serum	Children on gamma globulin
Intimate	121	129
Close	73	66
Remote	21	17
Total	215	212

Intimate = contacts who played &c. in the same section of the nursery as the primary case.

Close = children in other sections of the nursery who were exposed for short periods e.g. at play or at meals.

Remote = contact usually confined to exposure in the entrance hall in the morning or evening or out of doors during the day.

TABLE IV—CASES IN INOCULATED CONTACTS IN THE GLOBULIN AND ADULT SERUM GROUPS

—	Difference = 21.7 Standard error = 5.17 = 4.2				Difference = 44.2 Standard error = 10.24 = 4.3			

Scope of Inquiry

Trials were carried out in 48 nurseries, of which 6 were residential (table I). In all, 457 children were given adult serum and 464 gamma globulin. In 15 nurseries no contacts developed measles within twenty-one days after inoculation. In the 33 nurseries in which measles developed within the prescribed period there were 215 children in the adult serum groups and 212 in the gamma globulin group (table I), only the results in these children were analysed. In 27 of these nurseries, children in the globulin group were given 225 mg. of gamma globulin if under the age of 2 years and 300 mg. if between 2 and 5 years, in 6 nurseries all children in the globulin group were given 450 mg. All children in the comparative groups were given 5 ml. of adult serum.

Comparability of Globulin and Adult serum Groups

At the conclusion of the trials, the children in the globulin and adult serum groups were classified by age, sex, and intimacy of exposure, and the two groups were found to be comparable (tables II and III).

RESULTS

Attack rates (table IV)

In the nurseries where measles developed within twenty-one days after inoculation and where the dosage of gamma globulin was 225-300 mg., the attack rate was 33.7% in the globulin group and 55.4% in the adult-serum group. Where the dosage of gamma globulin

TABLE V—CHARACTER OF MEASLES RASH IN THE INOCULATED CHILDREN

Type of macules*	Children on adult serum			Children on 225-300 mg gamma globulin			Children on 450 mg gamma globulin

None	0	0	4	3	1	21	1	—	—
Total	121	121	121	58	58	58	8	8	8

* Note. In tables V-VII 2 cases on adult serum and one case on globulin have been omitted because the course of the disease in these cases could not be accurately assessed. It was however definitely established that they developed measles within 21 days and they have therefore been included in tables I-IV.

was 450 mg. the attack rate was 21.6% in the globulin group and 65.8% in the adult serum group, the numbers in the latter trials were small—37 in the globulin group and 38 in the adult serum group. The differences in attack rates in the two groups in both sets of trials were statistically significant.

Modification of Severity

Three criteria were used to assess the degree of modification in children who developed measles after inoculation—the character and distribution of the rash, the duration of the prodromal period, and the opinion of the observer on the severity of each attack as a whole. It was felt that in trials of this nature, where regular temperature recordings could not be obtained and where the number of visits which could be paid to the homes of the patients was limited, these were the only criteria which could be satisfied in all cases. As was mentioned, all observations were made and recorded without the observer knowing whether the case was in the globulin or adult serum group.

(a) *Character of rash*—In each case an attempt was made to assess the number and appearance of macules on the face, trunk, and limbs when the rash was most pronounced in these areas (table V). Of the 121 children on adult serum 78%, 77%, and 38% showed semi-confluent or numerous discrete macules on the face, trunk, and limbs respectively, the corresponding ratios for the globulin group on 225-300 mg. were 22%, 26%, and 9%, while none of the 8 children on 450 mg. of gamma globulin developed a rash to this extent.

TABLE VI—DURATION OF PRODROMAL SYMPTOMS IN THE INOCULATED

Duration (in hours)	Children on adult serum	Children on 225-300 mg gamma globulin	Children on 450 mg gamma globulin
No prodromals	1 (0.8%)	7 (12%)	4 (50%)
< 24	12 (9.9%)	22 (38%)	4 (50%)
24 -	46 (38%)	18 (31%)	—
48 -	30 (25%)	4 (6.9%)	—
72 +	32 (26%)	7 (12%)	—
Total	121	58	8

(b) *Prodromal symptoms*—The globulin and adult serum groups differed considerably in the duration of the prodromal stage. In the globulin group on 225-300 mg. of gamma globulin, 29 children (50%) had no prodromal illness or one lasting less than twenty-four hours before the appearance of the rash, in the adult serum group only 13 children (10.7%) were placed in this category, none of the 8 children who developed measles after 450 mg. of gamma globulin had a prodromal period exceeding twenty-four hours (table VI).

(c) *Observer's opinion of severity*—The type of rash and duration of prodromal symptoms did not always give a satisfactory measure of the degree of modification. Some children had a well marked rash with no apparent constitutional disturbance or pyrexia. In each case of measles following inoculation therefore an attempt was made to assess the degree of modification by taking all clinical findings into account, and each child was assigned to one of four categories, as follows:

Excellent modification minimal rash, prodromal symptoms very slight or absent, no catarrh or constitutional upset.

Satisfactory modification rash, catarrhal symptoms, and constitutional upset only slight, with rapid recovery.

Doubtful modification symptoms and signs that could not readily be distinguished from a mild attack of the natural disease.

No modification indistinguishable from a natural typical attack.

Table VII shows that in 93% of cases following 225-300 mg of gamma globulin and in all of the 8 cases on 450 mg the signs and symptoms were readily distinguishable from those of the natural disease, whereas in the adult serum group only 51% of cases showed significant modification. This difference is clearly (and technically) very unlikely to have arisen by chance.

TABLE VII—GENERAL ASSESSMENT OF CASES OF MEASLES IN THE INOCULATED

Prophylactic	Total cases	Excellent modification	Satisfactory modification	Doubtful modification	No modification
Adult serum	121	13 (10.5%)	49 (40.5%)	34 (28%)	25 (21%)
Gamma globulin 225-300 mg	58	33 (57%)	21 (36%)	2 (3.4%)	2 (3.4%)
Gamma globulin 450 mg	8	8 (100%)			

Complications

In the adult serum group, 5 children developed complications, 1 had bronchopneumonia, 1 gastroenteritis, 1 acute otitis media, 1 purulent conjunctivitis, and 1 bronchopneumonia with purulent conjunctivitis, all recovered.

In the globulin group, complications occurred in 2 children, both on the 225-300 mg dosage, one developed a recrudescence of a chronic otitis media fourteen days after recovery from a modified attack of measles, the other, who had recently had tonsillitis, developed otitis media and cervical adenitis two days after the rash appeared.

Reactions

Apart from transient stiffness of the limb lasting one or two hours after inoculation in a few cases, no local reactions were observed in the globulin or adult serum groups. One child in the globulin group developed, three days after inoculation, an urticarial rash which disappeared in twenty-four hours.

DISCUSSION

Effectiveness of Gamma Globulin and Adult Serum

Analysis of the results obtained indicates that gamma globulin prepared by an ether fractionation method is

TABLE VIII—EFFECT OF DEGREE OF EXPOSURE ON THE OCCURRENCE OF MEASLES IN ALL DAY NURSERY SECTIONS IN WHICH SUSCEPTIBLE CONTACTS WERE INOCULATED WITH GAMMA GLOBULIN AND ADULT SERUM

Day nursery section	Contact with infective case		
	Intimate*	Close*	Remote*
Sections where measles developed	26	12	3
Sections where measles did not develop	16	23	19
Total	42	35	22

* For definitions see table III.

a valuable agent in measles prophylaxis, when given in adequate doses to exposed susceptible contacts within three days of the appearance of the rash in the infecting case it will either prevent or modify the disease in nearly every case. Adult serum in 5 ml doses, though inferior to gamma globulin in its protective and attenuating action, results in some modification of the attack, in this investigation, 51% of the cases of measles in the serum treated group were classed as modified.

Dosage of Gamma Globulin

The optimum dose to prevent or modify measles depends on many factors. During the trials it was found impossible to predict for any individual child whether prevention or modification would result. This variation in individual susceptibility, previously noted by Stokes and his associates (1944), makes it difficult to construct a dosage table applicable to all children. Some American workers based their dosage on body-weight, but it was found less difficult and equally satisfactory to base the dosage for children on age. It was clear that gamma globulin in doses of 225-300 mg prevented measles in some cases, but it could not be relied on to prevent the disease in all children under 5 years of age. The attack-rates for children on 450 mg of gamma globulin and on 5 ml of adult serum were, for those aged 6-23 months, 6.3% and 43.8%, and for those aged 24-60 months, 33.3% and 77.3% respectively, in neither group therefore did 450 mg assure protection.

Supply of Gamma Globulin

In view of the complexity and cost of producing human gamma globulin it seems that it will have to be reserved for contacts in hospitals, and for children whose health is such that an attack of measles would endanger their life. For general use, adult serum or plasma will still have to be relied on.

Duration of Passive Immunity

In some nursery trials in one area, where the children were observed for more than twenty-one days after inoculation with 225-300 mg of gamma globulin, modification occurred up to six weeks, though its degree decreased rapidly towards the end of this period. With a dose of 450 mg, the duration of protection was more apparent, in one residential nursery trial, during the period 22-42 days after inoculation, 1 out of 15 remaining susceptible contacts in the globulin group developed measles after re-exposure, compared with 7 out of 3 in the adult serum group, and in another, where the same dosage was used, none of the 10 remaining susceptible contacts on gamma globulin developed measles, compared with 4 out of 7 on adult serum.

These observations support the view (Janeway 1944) that dosage is an important factor in determining the duration of passive immunity, and that, given in adequate doses, gamma globulin may prevent or modify the disease for more than three weeks after inoculation.

Effect of Degree and Intimacy of Exposure

Most of the day nurseries in which trials were carried out were divided into three sections. Susceptible contacts in the same section as the primary infecting case were in nearly all instances intimately exposed, whereas children in other sections were exposed less intimately.

The effect of the degree of exposure on the occurrence of measles in susceptible contacts who were inoculated with gamma globulin and adult serum in 99 separate day nursery sections is shown in table VIII. One or more cases of measles occurred in 26 (61.9%) of the 42 nursery sections in which "intimate" contacts were inoculated, in 12 (34.3%) of the 35 sections where "close" contacts were inoculated, and in 3 (13.6%) of the 22 sections in which remote contacts were inoculated.

These results suggest the need for consideration before inoculating remote contacts in nurseries. The risk of such contacts developing measles from the primary case appears to be small, and in view of the need for economy in measles prophylactics, it may be advisable to postpone inoculation in such cases until the children are more intimately exposed to secondary cases.

Infectivity of Measles

During the investigation, 9 day nurseries were observed in which the primary infective case had been absent.

from the nursery for sixty to seventy two hours before the rash appeared. Although none of the susceptible contacts in these nurseries had been inoculated, only 1 child developed measles within twenty one days after exposure. It seems therefore that measles was not readily transmitted in day nurseries by cases which were isolated 2½-3 days before the appearance of the rash. In some instances children who developed well modified attacks after gamma globulin were permitted to return to the nursery seven days after the appearance of the rash, and no secondary cases resulted.

Loss of Potency of Crude Globulin on Storage

In the preliminary investigation a batch of crude globulin held as a fluid was stored at 4°C from March, 1947, to January, 1948. It was used in March, 1947, and gave satisfactory modification. When used in January, 1948, it had lost potency, and in 9 out of 17 close contacts who developed measles within twenty one days of inoculation there was no evidence of modification. In contrast, a similar dried batch of globulin retained its potency over the same period. For this reason all subsequent batches were dried and reconstituted immediately before use.

RECOMMENDATIONS

On the basis of the results obtained in the trials the following dosage schedule is suggested

Age of children (mos)	Dosage of gamma globulin (mg) where		
	modification is desired	prevention is desired	prevention is essential
6-23	150-225	450	675
24-59	225-300	675	900

The inoculation should be given within seventy two hours of the appearance of the rash in the primary infecting case, where this is not possible the dose may have to be increased.

SUMMARY

In a series of controlled trials in day nurseries, gamma globulin was given in 225-450 mg doses to 212 susceptible measles contacts between the ages of 6 months and 5 years, 31.6% developed measles and 94% of these showed excellent or satisfactory modification. Adult serum was given in 5 ml doses to 215 contacts of similar age and exposure, 57.2% developed measles, and 48.9% of these showed no (or doubtful) evidence of modification.

The attack rates for children receiving 225-300 mg and 450 mg of gamma globulin were 33.7% and 21.6% respectively, whereas in the corresponding groups of children receiving 5 ml of adult serum the rates were 55.4% and 65.8%. The duration of passive immunity depended on dosage, with the larger dose some protection for periods up to six weeks was observed.

Recommendations are made on the dose of gamma globulin to be given to exposed children at different ages to modify or prevent an expected attack of measles.

Reactions to the prophylactic injections in this trial were minimal and unimportant.

No serious complications were observed in the globulin group.

STERILITY DUE TO CONGENITAL ABSENCE OF THE VASA

BERNARD SANDLER

M D Manc, D M R, D Obst

MEDICAL OFFICER TO THE SUBFERTILITY CLINIC,
MANCHESTER VICTORIA MEMORIAL JEWISH HOSPITAL

IN 1948 Young reported a case of congenital absence of the vas as being the first on record in this country.

In America Engle (1947) noted the condition, Michelson (1947a) reported the vas absent in 4 (3%) of 80 cases of azoospermia, while both Simmons (1945) and Charny (1945) put the incidence at about 5%. Mazer and Isaacs (1941) in 308 cases of male infertility, found 45 due to obstructive azoospermia, of which 4 were due to congenital atresia. The German author Drrr (1940) gave the incidence of atresia as approximately 0.05% in all operations on the vas.

The difference in these figures may be due to the fact that the Germans were sterilising normal fertile males as part of their fantastic racial purity campaign, while American cases were all from subfertility clinics.

In Franco, Laffont and Ezes (1949) report the condition but say that in half the cases it is possible to do an anastomosis, which in half of these is successful. Such a success rate is not equalled in reports from clinics in other countries. Bayle (1950) reports an incidence of 4% with 65% cures.

At the Conference on Sterility held in Edinburgh in September, 1949, Tulloch said that the condition is commoner than hitherto believed, and his incidence rate would probably have been higher if he had not regarded the presence of a palpable cord as evidence that the vas is patent. As the following case shows, it is not reliable evidence.

CASE REPORT

A man, aged 29 who had been married 4 years, attended the clinic in June, 1949 because of sterility. Azoospermia had been diagnosed in May, 1949, and confirmed in three successive specimens. He had normal coitus three times weekly, with satisfactory orgasm both for himself and his wife. The wife had been examined at another hospital, and as she was said to be "small," curettage had been arranged, although the diagnosis of azoospermia had been originally made there!

The man was of normal spare build, with normal hair distribution and adult male voice. There was no evidence of pituitary or other endocrine dysfunction. There was a small left varix. Both testes were in the scrotum, they were small and soft, but testicular sensation was present. Tissues resembling cords were palpable on both sides. The penis was normal in size and shape. I performed a testicular biopsy which revealed active spermatogenesis in both testes. In view of this I advised exploration, which was undertaken by Mr H M Goldberg, F.R.C.S., to whom I am indebted for his help.

Operation—On delivering the testes through an incision in the upper part of the scrotum, it was seen that both epididymes were small, flattened, and not of the usual shape. The right globus major appeared normal. The lower half of the body and the tail were composed of greatly dilated, thin walled ducts, filled with a yellowish creamy material. The right spermatic cord was examined, but no trace was found of the vas, or of any rudimentary structure resembling it. On the left side an extremely thin rudimentary vas was found with much difficulty. The lumen was so small that it admitted only a fine hypodermic needle. An attempt was made to inject methylene blue to determine the patency of the ejaculatory duct. The lower pole of the left epididymis showed changes similar to those on the other side. Microscopically the material aspirated from the right side consisted of amorphous debris and spermatozoa were not seen.

The tunica albuginea of the left globus major was incised, and the underlying tissue gently opened up. Confirmation that this tissue contained some seminiferous tubules was obtained by pressing a glass slide on the epididymal tissue and finding active spermatozoa under the microscope. These spermatozoa survived more than 2 hours.

A longitudinal incision into the rudimentary vas was made, and the edges were anastomosed to the edges of the tunica

albuginea Unfortunately subsequent semen analysis has not revealed the presence of spermatozoa Presumably the vas was too rudimentary to perform its function, or anastomosis was unsuccessful

METHODS OF TREATMENT

Much work is now being done, particularly in America, on the best method of performing anastomosis But the successful results reported by some authors (Cameron 1945, Michelson 1946), are for anastomosis of tubes which were originally normal but later became occluded (e.g., after gonorrhoea or by vasectomy) In congenital atresia, on the other hand, maldevelopment may not be confined to the vas, and often extends to other genital structures Though the actual anastomosis may be successful in these cases, anatomical defects elsewhere may prevent spermatozoa from appearing in the semen

To keep the anastomosis open, various ingenious methods of utilising silver wire, 'Nylon,' and other materials have been devised (Hagner 1936, Michelson 1946, 1947b and c)

When operation fails, what can be done? Some workers (Schultze 1941, Guttmacher 1942, Sangree 1947) have tried the insemination of sperm obtained by aspiration of the epididymis, but without success Lespinasse (1947) has advocated the opening of the epididymis so that spermatozoa may flow freely into the tunica vaginalis, but he does not say what success has followed It does seem very tragic that when live spermatozoa can be demonstrated in the epididymis they cannot be used for insemination The work of Henle and Zittle (1942) throws some light on the reason for failure

Comparing the metabolism of epididymal and ejaculate spermatozoa in the bull, they found a remarkable change Whereas glucose can be oxidised rapidly by epididymal spermatozoa, in the ejaculate there was no oxidation of glucose at all—in fact the addition of glucose depressed oxidation

Spermatozoa living in germinal epithelium must have energy processes more economical to the substrate These spermatozoa begin their development with all these complex mechanisms present, which become 'hangovers' in ejaculate spermatozoa Thus the cytochrome (respiratory) system persists in ejaculate spermatozoa, though they do not respire in the ejaculate It would be much more economical for spermatozoa to use the energy of respiration The breakdown of glucose to lactic acid to give energy is most wasteful (McLeod 1946) for ten times as much sugar is used to get a unit of energy by that method than by the oxidation of a molecule of glucose

In this connection the presence of adequate carbohydrate in normal cervical mucus as a natural occurrence is of special significance The absence of such carbohydrate has been shown (Barton 1948) to be a factor in certain types of infertility

It would seem that epididymal spermatozoa are not equipped to live in the cervix until they have developed their new method of metabolism—any more than a foetus removed from the uterus can survive before it has developed an adequate respiratory system through the lungs The best hope for the future lies in the biochemist providing us with a substrate in which epididymal spermatozoa could live until such time as they have perfected their mechanisms for living like ordinary mature spermatozoa, by the breakdown of glucose to lactic acid

SUMMARY

A case of sterility with azoospermia due to congenital atresia of the vas is described Active spermatogenesis was present in both testes Vaso epididymal anastomosis was attempted without success This condition is more frequent than is generally supposed, and should be sought in all cases of azoospermia where there is no history of infection

APLASIA OF THE VASA DEFERENTIA AS A CAUSE OF STERILITY

GEORGE L FOSS

V.R.D. M.A., M.D. Camb

CLINICAL ASSISTANT DEPARTMENT OF MEDICINE AND GYNECOLOGICAL OUTPATIENT DEPARTMENT, BRISTOL ROYAL HOSPITAL

ASHTON MILLER

M.A., M.D. Camb, F.R.C.S.

LECTURER IN SURGERY IN THE UNIVERSITY OF BRISTOL, CONSULTANT SURGEON, BRISTOL ROYAL HOSPITAL

In the routine investigation of 200 cases of male infertility during the last four years bilateral aplasia of the vas deferens was found in 3 otherwise normal men. If careful search were made for the condition, it would probably prove to be a commoner cause of absolute sterility than is suggested by the number of published reports

Demel (1926) reviewed 12 recorded cases In 7 the seminal vesicle, ejaculatory duct, kidney, and ureter, as well as part or all of the epididymis and vas deferens on one side had not properly developed In most of these only the globus major or head of the epididymis was present, in 2 cases the body of the epididymis was also present, and in 1 case only a vestige of the epididymis was found In all the testes spermatogenic tissue was present and normal Blecher (1931) also reported 6 cases, and Priesel (1924, 1931) 1 case

The Nazi habit of sterilising men for various reasons provided a great opportunity for discovering this congenital defect, and Vorstoffel (1937), in a review of the German literature up to 1936, found records of 22 cases of complete or partial absence of the vas deferens, these included 2 cases in which the vas deferens on both sides was a slender fibrous cord, 2 in which the vas deferens and epididymis on both sides were missing, and 2 with normal testes and epididymis but no vas deferens and kidney on one side

Dirr (1940) reported 2 cases of unilateral absence of the vas deferens in a series of 45 ligations, and stated that the incidence of this anomaly was 0.5% in all operations of this type in Germany Olesen and Faber (1944) described 2 cases of bilateral aplasia

Charny (1946), discussing his findings in 308 men subjected to testicular biopsy for impaired fertility, reported 4 cases of congenital absence of the vasa deferentia in patients with azoospermia and normal spermatogenesis In an analysis of 146 cases of azoospermia Michelson (1947) found that clinically there was bilateral absence of the vasa in 4 patients, but that this was confirmed in only 1 case

Young (1949) was the first to report a case in this country. He describes the findings in an infertile man, aged 28, with azoospermia, absence of fructose in the semen, and normal spermatogenesis as shown by testicular biopsy. No abnormality of the vasa was noted clinically, but after careful exploration thin fibrous cords were found on both sides, and no lumen in this tissue was found microscopically. Young discusses the embryology of the genital tract and points out that, if development is disturbed before the 60 mm stage, it is possible to have a fully developed testis and epididymis with an undeveloped vas deferens, ejaculatory duct, and seminal vesicle. If the epididymis is present it is unlikely that the vas is ever completely absent; it is more likely to be present in an undeveloped state. If the vas is undeveloped, it is impossible to have a normal seminal vesicle or ejaculatory duct.

Michelson (1949) reported 12 abnormalities of the vas in 900 subfertile men; 11 of these were bilateral. In 8 cases, however, he did not confirm these findings by operative exploration and in 1 of the operated cases only one side was examined. He cites personal communications from R. S. Hotchkiss, who had 20 cases, and F. A. Simmons, who had about 8 with the same incidence.

Kenneth Walker, at the meeting of the Fertility Society this year, drew attention to this anomaly and said he had seen several cases.

PRESENT SERIES

Of the 200 men investigated, 37 (18%) proved to have complete azoospermia. Bilateral aplasia of the vas was the cause in 3 of these, which is an incidence of 1.5% in the total series and 8% in the patients with azoospermia. Excluding from the 37 patients 21 who had testicular agenesis, bilateral cryptorchism, tuberculous epididymitis, or atrophy following surgical attempts to bring down undescended testes, we are left with 16 who had testes of normal size on clinical examination, and among these the incidence of bilateral aplasia of the vas deferens was 18%.

CASE RECORDS

Case 1—An electrical engineer, aged 39, who had been married for six years without begetting any children, was referred for routine examination. There was no history of venereal disease or injury, and no family history of impaired fertility. His sexual development had been normal, and there were no abnormalities of sexual technique or function; orgasm occurred rather rapidly, with an outwardly normal seminal emission.

On examination the patient was a strong healthy man. His penis and both testes were normal in size and shape, and testicular sensation was present on pressure. The upper poles of the epididymis on both sides felt cystic, but no abnormality of the cord or vas was noted at the time.

Semen—Two masturbation samples of semen were of small volume, 1 or 2 ml, consisting of abnormally clear mucoid fluid. There was complete azoospermia after centrifuging, and the fluid only contained a few lipid granules, probably of prostatic origin.

Biopsy of both testes was carried out under thiopentone anaesthesia, using the punch described by Friedmann (1948), and sections showed that spermatogenesis, although not very vigorous, was active. There was no hyalinisation of the capsules or fibrosis of the interstitial tissue.

Surgical Exploration (A.M.)—The testes were both normal, but the upper pole of the epididymis on both sides was cystic. Puncture of the epididymes with a needle and immediate microscopy revealed plenty of active and apparently normal spermatozoa. There were no bodies or tails to the epididymes, and both vasa were completely absent.

It was hoped to attempt artificial insemination by puncture of the cystic epididymes at the appropriate time in his wife's cycle, but the couple, perhaps wisely, decided to adopt a child.

Case 2—This patient, a general warehouseman aged 29, had been married for four years before he decided to be investigated. There was no history of previous illness and no infertility in his family. He had developed sexually at the

age of 12 years; masturbation had been normal, as were sexual technique and function.

On examination he was of rather slim build but otherwise healthy. His penis was normal and circumcised. Both testes were equal in size, of good shape, and firm, and normal testicular sensation was elicited on pressure. The upper pole of the epididymis on both sides was enlarged and soft, and the lower pole could not be felt. The vas could not be palpated in the scrotum on the right side, but a normal vas was palpable on the left.

Semen—Two seminal analyses showed an abnormally clear and slightly milky fluid (volume not recorded). Spermatozoa were absent from both.

Testicular biopsy on both sides was carried out under light thiopentone anaesthesia. On section the tubules of both testes were thin walled and well filled with active spermatogonia and spermatoocytes, many tubules containing numerous adult spermatozoa. The interstitial tissues, particularly on the right side, showed some fibrosis.

Surgical Exploration (A.M.)—On the left side the vas, which appeared normal, was easily traced down to the level of the upper pole of the epididymis where it ended suddenly; there was a tenuous fibrous cord connecting it to the region of the body of the epididymis. The lower pole of the epididymis was absent and only the upper pole and body were identified. On the right side no vas was found in the scrotum, and only the upper pole of the epididymis was present.

Case 3—A plate layer, aged 40, had been married for fourteen years, and he and his wife had already adopted one child. As a last hope he presented himself for investigation. There was no history of illness or venereal disease, and he and his two brothers and three sisters all had large families. Sexual development had occurred normally at the age of 13, and he was fairly sure that as a youth he had produced a reasonable amount of fluid on masturbation. Now, however, although sexual sensation was normal at coitus, orgasm was an odd stinging sensation and he had no feeling of emission. Masturbation had since shown that the emission consisted of a little sticky moisture.

Examination—He was of slight build and healthy. His penis was circumcised and normal in size. Both testes were large and firm, with cystic upper poles of the epididymes. No vasa could be felt, so bilateral aplasia was diagnosed. The diagnosis was so certain that seminal analysis and testicular biopsy were made on the same day. The former showed only a few drops of whitish fluid. No spermatozoa were seen in the direct smears, and the specimen was insufficient for further examination.

Testicular biopsy showed normal spermatogenesis in the right testis, but on the left side the tubules were distorted and fibrosed, few adult spermatozoa being seen.

Surgical Exploration (A.M.)—There was no sign of a vas on either side between the external abdominal ring and the lower pole of the epididymis, which was slightly larger than normal owing to multiple small cysts, mostly in the upper pole, on both sides.

SUMMARY

Three cases of bilateral aplasia of the vas deferens were found among 200 males investigated for possible infertility; this is an incidence of 1.5%. Further analysis shows an incidence of 8% in cases with azoospermia, and of 18% in cases with azoospermia and clinically normal testes.

As a possible cause of sterility, aplasia of the vasa deferentia should be more generally borne in mind.

Our thanks are due to Dr. A. L. Taylor for seminal analyses and for reports on the testicular biopsies, and to the members of the consulting staff of the Bristol Royal Hospital for referring cases.

LIQUEFACTION OF VISCOS PURULENT EXUDATES BY DEOXYRIBONUCLEASE

JOHN B ARMSTRONG

M.D. Toronto

J C WHITE

M.B. Birmingham

JUNIOR REGISTRAR IN MEDICINE LECTURER IN HEMATOLOGY
POSTGRADUATE MEDICAL SCHOOL OF LONDON

IN VITRO experiments and a few clinical observations have been made on reduction in the viscosity of purulent sputa and pleural exudates by the action of the enzyme deoxyribonuclease (D.N.P.) derived from ox pancreas. The enzyme is acting here on extracellular hydrated fibrils of deoxyribonucleoprotein (D.N.P.). The basis of this work is as follows

Basis of Cellular Nucleic Acids—In 1868, Miescher isolated deoxyribonucleic acid (D.N.A.) from pus cells. Considerable evidence now indicates the importance of both this substance and ribonucleic acid in all living cells (Brachet 1942, Caspersen 1947, Davidson 1949). Physical and chemical differences exist between the two acids, and solutions of D.N.A. and D.N.P. are much more viscous than those of ribonucleic acid and ribonucleoprotein, probably owing to their highly polymerised macromolecular state (Gulland and Jordan 1947).

Enzymes Degrading Nucleic Acids—Specific enzymes degrade both acids. D.N.P. is widely distributed—e.g., in rice bran (Serra and Queiroz Lopes 1944), yeast (Zamenhof and Chargaff 1949), and certain haemolytic streptococci—and is usually obtained pure from beef pancreas by the method of McCarty (1946) or crystalline by that of Kunitz (1950).

When activated by magnesium or certain other ions the enzyme rapidly reduces the viscosity of D.N.A. or D.N.P. solutions, the action being apparently a depolymerisation (Greenstein et al. 1947, Jungner 1950).

D.N.P. action on fixed cells is readily demonstrated cytochemically (Brachet 1942, Sanders 1946, Catcheside and Holmes 1947, Davidson 1947, Brachet and Shaver 1948, White 1950). The nucleases do not, however, act on living cells (Davidson et al. 1948, Elv and Ross 1949), but nucleic acids in extracellular accumulations and in disintegrating cells are readily affected.

Viscosity of Pus, and its Reduction by Streptococcal Enzymes—Since 1933 Tillet has devoted a great deal of study to the fibrinolytic activity of haemolytic streptococci. In the course of these investigations Sherry et al. (1948) have shown that in many purulent pleural exudates fibrin may be a less important cause of thickness and viscosity than D.N.P., which may constitute 30–70% of the total solids present. Tillet et al. (1948) have demonstrated further that the D.N.P. may be liquefied by streptodornase, a D.N.P. present in concentrates from cultures of haemolytic streptococci, particularly of group A. This enzyme is quite distinct from the concomitant streptokinase, a fibrinolytic which liquefies fibrin clots. Dramatic clinical improvement has been described following the injection of such concentrates into the pleural cavity of patients with fibrinous purulent, and sanguineous pleural exudates (Tillet and Sherry 1949, Sherry et al. 1949), and after "streptococcal enzymatic debridement" of infected surface areas (Tillet et al. 1950, *Lancet* 1950).

Extracellular Fibres of D.N.P.—Fibres seem to be formed readily by the alignment of the D.N.A. or D.N.P. macromolecules. This may well be important in chromosome structure (Astbury and Bell 1938, Mazia et al. 1947, Bateman 1947).

Under various conditions an apparently thixotropic change (gel→sol→gel) leads to the formation of fibres or of rods from whole cell nuclei:

(1) Rod like nuclear extrusions at the periphery of some cutting diathermy and aspiration biopsies

(2) Isolated leukaemic nuclei transformed into cylinders by application of pressure

(3) A viscous mass of fibres forms when leukaemic lymphocytes are stirred into molar sodium chloride for D.N.P. preparation by the method of Mirsky and Pollister (1946). These finally disperse into solution and D.N.P. fibres ('chromosome') again precipitate on pouring into 6 volumes of water.

(4) Simple storage of leukaemic cells in their plasma for three weeks at 5°C can yield a viscous mass of D.N.P. fibrils derived from the nuclei.

In all instances a positive Feulgen reaction indicates that the fibres contain D.N.A. Although physical forces operate in examples (1) to (3), in (4) the cells were undisturbed, but autolytic enzymatic changes may have played a part.

VISCOSITY OF SPUTUM AND D.N.P.

Many samples of purulent sputum possess great viscosity and resistance to flow, and on cytochemical examination prove to have a fibrillar structure due to D.N.P. and similar to the examples previously detailed. Movement due to respiration, coughing and ciliary action may all play a part in forming fibres from leucocyte nuclei and the result is a mass which is expectorated only with difficulty.

Thorough centrifugation of such sputa produces the classical three layers. Cytochemical examination shows that the topmost layer is clear and viscous, only a few mm in depth, and contains a minimum of cellular and fibrillary material demonstrable with the Feulgen stain, though a good deal of coagulated protein without D.N.A. is present, the bottom layer is granular, and the Feulgen stain reveals many leucocytes and coarse strands of Feulgen positive material, and the middle layer, which is by far the most copious, is an extremely viscid mass of vertically oriented fibrils attached to the bottom layer and entangling intact leucocytes. Phase contrast microscopy also clearly reveals these fibrils both in centrifuged sputum and in fresh unsmear sputum. This seems to dispose of the possibility that the fibrils are formed as a smear or fixation artefact, though fixation will alter the state of their hydration.

The work presented here is largely concerned with rendering such purulent sputum more liquid by the action of D.N.P., and with the possibility of administering the enzyme by spray inhalation to patients with chronic bronchitis, bronchiectasis, and similar chest disorders in which tenacity and high viscosity of the purulent material presents difficulty in management.

METHODS

Deoxyribonuclease

The enzyme D.N.P., was isolated from beef pancreas by the method of McCarty (1946) and freeze dried. The preparation principally entails repeated fractionation with the aid of ammonium sulphate, and is lengthy but requires little expensive apparatus or reagents. We are, however, grateful to Mr E. G. Wright of the Government Research Institute, Weybridge for freeze drying our final dissolved solution of purified enzyme. The resulting white solid soluble enzyme was stored in vacuo at 5°C. A yield of about 2.5 g of dry enzyme was obtained from 10 kg of pancreas.

Tests for toxicity to rabbits were made by intravenous injection (20 mg in each of two injections at an interval of ten days) and intratracheally. There were no demonstrable toxic effects, but serum taken ten days after the second intravenous injection gave a precipitin reaction with D.N.P. and inhibited the enzyme activity to a considerable extent cytochemically, suggesting the development of an antibody. The specificity of these reactions is now being investigated.

Stock solutions of the enzyme were made, up at a concentration of 0.05 mg per ml or more, in M/50 MgCl₂ solution containing 1% gelatin. The magnesium

Fig 1—Photomicrographs of sputum wet fixed in Susa solution and Feulgen-stained: (a) purulent sputum showing Feulgen positive fibrils arranged in strands and entangling leucocytes; (b) non-purulent mucinous sputum showing Feulgen reaction confined to nuclei of leucocytes, which are embedded in muco-protein ($\times 100$)

ion is an obligatory activator, and the gelatin protects the unstable enzyme in solution. The fresh solution was sterilised by Seitz filtering, dispensed in 5 ml bottles, and stored at 5°C . Full bacteriological tests for sterility were made through the kindness of Dr W Hayes and Dr G I M Ross.

Cytochemical Tests

For investigating the action of the enzyme we have used a technique previously found reliable in the study of cellular nucleoproteins (White 1947, 1950). D N A se activity was very high, and proteolytic activity not appreciable at enzyme concentrations up to 0.2 mg per ml, though slight proteolysis occurred at higher concentrations. No appreciable fibrinolytic activity was shown at a final concentration of 0.5 mg per ml, only slight softening of the fibrin clot, without any liquefaction occurred after eighteen hours at 37°C .

The sputum samples were smeared on to glass slides and fixed while wet in Susa solution for an hour. Wet preparations of blood cells or other test preparations were fixed in the same way. In the *in vitro* experiments the slides were covered with test enzyme solution or control solution minus enzyme, and kept at room temperature, or at 37°C , for an hour or more. Next they were washed and stained by the pyronin methyl green or Feulgen methods. The latter is generally considered a highly specific cytochemical test for D N A (Feulgen and Rossenbeck 1924), and the former method gives a useful and reliable distinction between the two forms of nucleic acid (Brachet 1942).

In the Feulgen preparations of purulent sputa long fibrils of Feulgen positive material are to be seen running between the leucocytes and enmeshing them. In comparative studies changes in the number and structure of these fibrils are readily appreciated on high power microscopy.

Viscosity Measurements

It is evident that the presence of fibrils confers a structural

rigidity rather than a true solution viscosity on the sputum, rendering straightforward viscometry very difficult.

Comparative measurements of the viscosity of the sputum samples were estimated on a modification of the ball viscometer described by Lucas and Henderson (1936), using 9.5 cm of a tube of bore 6 mm, and a ball bearing of 3 mm diameter (weight 2.0 g) or 0.25 ml of mercury (weight 3.4 g). As Lucas and Henderson found with saliva, the viscosity of sputum decreases with time after collection, rapidly at body temperature but appreciably at 5°C . The decrease is presumably due to enzyme activity within the sample, and this made serial studies on fresh material from patients practically impossible. One spasm of coughing seldom produced sufficient for making estimations with the equipment described. But controlled *in vitro* studies or mixed samples of relatively fresh sputum enabled significant differences to be detected.

Inhalation Spray

The D N A se was made up in various strengths—0.05 mg and 0.5 mg per ml—in $M/50$ MgCl_2 with 1% gelatin, Seitz filtered and stored in 5 ml quantities at 5°C till used. The lowest concentration was found too low for consistent clinical results, though a cytochemical effect was obtained. The efficacy of the spray was demonstrated beforehand on fixed smears of cells. The higher concentrations proved more satisfactory clinically. The spraying apparatus was the commercially available 'Deedon,' modified to give a flow of vapour, through a 3 in glass tube of about 1 in diameter, directly into the mouth. A flow of 6–8 litres a minute of 5% carbon dioxide and 95% oxygen was supplied through a T tube. The other wing of the T was closed by the patient's thumb during inspiration and open during expiration, in the manner described by Barach (1945). In the

Fig 2—Photomicrographs showing effect *in-vitro* of deoxyribonuclease on Feulgen reaction of purulent sputum: (a) control sample after two hours incubation at 37°C showing many Feulgen positive fibrils and leucocytes; (b) sample of same sputum after action of deoxyribonuclease showing disappearance of Feulgen positive fibrils but persistence of intact cell nuclei ($\times 400$)

clinical trials the inhalation spray was administered once only or three times a day for two or more days, to a maximum of eleven inhalations for any one patient in this study. There was no contra-indication to longer administration. The enzyme was not inhibited by penicillin or streptomycin, in either the test tube experiments or the therapeutic spray as demonstrated cytologically.

RESULTS

Material from 15 patients has been studied. In 8 patients the sputum was studied by *in vitro* experiments using the enzyme DNase and suitable control solutions. Clinical appraisal of the enzyme effect was attempted in 7 patients, DNase being administered by inhalation spray to 6, and by intrapleural injection to 1.

In Vitro

Fig 1 compares the appearance of purulent sputum (a) with mucinous non purulent sputum (b). Fibrils are seen as ropes and strands which give a positive reaction to the Feulgen stain in the purulent specimen. Feulgen positive fibrils are not seen in the non purulent specimen though the cell nuclei, containing DNA, are stained, and the cells are embedded in mucoprotein. The effect of the enzyme DNase on the fibrils after incubation for two hours at 37°C is shown in fig 2, and compared with a control sample. In the enzyme treated specimen the Feulgen positive reaction of the fibrils has almost entirely disappeared, but the nuclei of many intact leucocytes have preserved their staining characteristics. After incubation for two hours at 37°C the viscosity of the enzyme treated sputum was reduced to 27% of the control.

In Vivo

Similar though not such extensive alterations in the fibrils were seen in the sputum samples obtained from 4 patients with purulent bronchitis, at suitable intervals after a single inhalation of 5 ml of the DNase solution. The lowest concentration (0.05 mg per ml) of enzyme was used first and found to have little clinical effect although there was demonstrable cytochemical change in the subsequent sputum. The first change seen was a diffuseness and then slight granularity in the Feulgen stained fibrils. Later the fibrils became fragmented, stained more weakly, and finally disappeared. In case 1 there were typical *in vivo* macroscopical and microscopical changes in the sputa after a single inhalation of DNase. Case 2 was a patient with empyema who was given two intrapleural injections of 0.25 mg of DNase at an interval of forty eight hours.

Case 1—A man, aged 75, had worked as a miner until five years ago. He had had fair health, except for a chronic cough and grey sputum for years. A month before admission cough and sputum had become much worse, and associated with dyspnoea.

Date	Clinical data and therapy	Cytochemical findings in sputum
Feb 6	Admitted with acute urinary retention. Chest rhonchi throughout, rales at both bases posteriorly.	—
Feb 14 12.30 P.M.	Coughing up greenish purulent sputum 8-10 oz daily. Vital capacity 800 ml. DNase 0.25 mg by inhalation spray.	—
		Control (before therapy) 8 A.M. to 12.30 P.M. a great many fine Feulgen positive fibrils

Fig 3—Photomicrographs of Feulgen-stained sputum from a patient with bronchiectasis: (a) control specimen expectorated before inhalation of enzyme showing leucocytes entangled in thick ropes of Feulgen-positive fibrils. (b) sputum expectorated the day after inhalation spray of deoxyribonuclease 5 mg showing disintegration and disappearance of Feulgen-positive fibrils with persistence of many free leucocytes ($\times 200$).

1.30 P.M.	Sputum slightly less viscid, no subjective change.	Little change though some fibrils less discrete and Feulgen negative ground substance more evident.
3.30 P.M.	Sputum little change.	Few Feulgen positive fibrils and these less discrete. Feulgen negative ground substance increased and free cells more evident.
Feb 15 8.45 A.M.	Sputum easier to bring up during the night no visible change in character.	Fibrils diffuse and weakly Feulgen positive background more cellular.
4.45 P.M.	Respiration easier sputum readily brought up.	Fibrils fragmented granular, and practically all Feulgen negative.
Feb 16 8.30 A.M.	Feels about same, no further change in sputum.	Short irregular fibrils reappearing but not deeply Feulgen positive.
Feb 17 9.00 A.M.	Sputum more viscid but not to control levels vital capacity 1250 ml.	Fibrils longer but not aligned in strands little ground substance.

Case 2—A woman, aged 56, with two weeks history of severe malaise, weakness, sweating, cough with little sputum, and pain in the left side of the chest.

Date	Clinical data and therapy	Cytochemical findings in pleural exudate
Jan 20	Admitted flushed and exhausted with dullness at left base. Radiography showed diffuse shadow in same area. Penicillin I.M. 500 000 units daily until Jan 24. Aureo mycin Jan 24-28.	—
Jan. 30	Chest aspiration 60 ml. of thick tenacious greenish pus giving lactose fermenting coliform bacillus in culture. Penicillin 500 000 units injected intrapleurally.	Fine thin strands of Feulgen positive material between deeply stained nuclei of enmeshed cells.
Jan 31	Chest aspiration 155 ml of thick ropy greenish exudate difficult to aspirate. DNase 0.25 mg in 10 ml. of saline solution injected intrapleurally with penicillin 1 000 000 units.	Appearances similar to above but Feulgen-negative ground substance slightly increased.
Feb 1	Chest aspiration 140 ml of moderately thick smooth pus running more readily through the needle.	Pus-cell nuclei still stain Feulgen positively fibrils thicker more diffuse and many fragmented.
Feb 2	Chest aspiration 120 ml of free-flowing greenish exudate giving profuse growth of <i>Bact. coli</i> on culture. DNase 0.25 mg in 10 ml. of saline solution and penicillin 1 000 000 units injected intrapleurally.	Fibrils infrequent, thin and discreet. Ground substance much more diffuse and cells relatively more numerous.

Fig 1—Photomicrographs of sputum wet fixed in Susa solution and Feulgen-stained: (a) purulent sputum showing Feulgen positive fibrils arranged in strands and entangling leucocytes (b) non purulent mucinous sputum showing Feulgen reaction confined to nuclei of leucocytes which are embedded in muco-protein ($\times 100$)

ion is an obligatory activator, and the gelatin protects the unstable enzyme in solution. The fresh solution was sterilised by Seitz filtering, dispensed in 5 ml bottles, and stored at 5°C. Full bacteriological tests for sterility were made through the kindness of Dr W Hayes and Dr G I M Ross.

Cytochemical Tests

For investigating the action of the enzyme we have used a technique previously found reliable in the study of cellular nucleoproteins (White 1947, 1950). DNase activity was very high, and proteolytic activity not appreciable at enzyme concentrations up to 0.2 mg per ml., though slight proteolysis occurred at higher concentrations. clinical trials the inhalation spray was administered once only or three times a day for two or more days, to a maximum of eleven inhalations for any one patient in this study. There was no contra-indication to longer administration. The enzyme was not inhibited by penicillin or streptomycin, in either the test tube experiments or the therapeutic spray, as demonstrated cytochemically.

RESULTS

Material from 15 patients has been studied. In 8 patients the sputum was studied by *in vitro* experiments using the enzyme D_Nase and suitable control solutions. Clinical appraisal of the enzyme effect was attempted in 7 patients, D_Nase being administered by inhalation spray to 6, and by intrapleural injection to 1.

In Vitro

Fig 1 compares the appearance of purulent sputum (a) with mucinous non purulent sputum (b). Fibrils are seen as ropes and strands which give a positive reaction to the Feulgen stain in the purulent specimen. Feulgen positive fibrils are not seen in the non purulent specimen though the cell nuclei, containing D_NP are stained, and the cells are embedded in mucoprotein. The effect of the enzyme D_Nase on the fibrils after incubation for two hours at 37°C is shown in fig 2, and compared with a control sample. In the enzyme treated specimen the Feulgen positive reaction of the fibrils has almost entirely disappeared, but the nuclei of many intact leucocytes have preserved their staining characteristics. After incubation for two hours at 37°C the viscosity of the enzyme treated sputum was reduced to 27% of the control.

In Vivo

Similar though not such extensive alterations in the fibrils were seen in the sputum samples obtained from 4 patients with purulent bronchitis, at suitable intervals after a single inhalation of 5 ml of the D_Nase solution. The lowest concentration (0.05 mg per ml) of enzyme was used first and found to have little clinical effect, although there was demonstrable cytochemical change in the subsequent sputum. The first change seen was a diffuseness and then slight granularity in the Feulgen stained fibrils. Later the fibrils became fragmented, stained more weakly, and finally disappeared. In case 1 there were typical *in vivo* macroscopical and microscopical changes in the sputa after a single inhalation of D_Nase. Case 2 was a patient with empyema who was given two intrapleural injections of 0.25 mg of D_Nase at an interval of forty-eight hours.

Case 1—A man, aged 75 had worked as a miner until five years ago. He had had fair health, except for a chronic cough and grey sputum for years. A month before admission cough and sputum had become much worse and associated with dyspnoea.

Date	Clinical data and therapy	Cytochemical findings in sputum
Feb 6	Admitted with acute urinary retention. Chest rhonchi throughout, rales at both bases posteriorly.	—
Feb 14 12.30 P.M.	Coughing up greenish purulent sputum 8-10 oz daily. Vital capacity 800 ml. D _N ase 0.25 mg by inhalation spray.	Control (before therapy) 8 A.M. to 12.30 P.M. a great many fine Feulgen positive fibrils.

Fig 3—Photomicrographs of Feulgen-stained sputum from a patient with bronchiectasis. (a) control specimen expectorated before inhalation of enzyme showing leucocytes entangled in thick ropes of Feulgen-positive fibrils. (b) sputum expectorated the day after inhalation spray of deoxyribonuclease 5 mg showing disintegration and disappearance of Feulgen positive fibrils with persistence of many free leucocytes ($\times 200$).

1.30 P.M.	Sputum slightly less viscid, no subjective change.	Little change though some fibrils less discreet and Feulgen negative ground substance more evident.
3.30 P.M.	Sputum little change.	Few Feulgen positive fibrils and these less discreet. Feulgen negative ground substance increased and free cells more evident.
Feb 15 8.45 A.M.	Sputum easier to bring up during the night no visible change in character.	Fibrils diffuse and weakly Feulgen positive, background more cellular.
4.45 P.M.	Respiration easier sputum readily brought up.	Fibrils fragmented granular, and practically all Feulgen negative.
Feb 16 8.30 A.M.	Feels about same no further change in sputum.	Short irregular fibrils reappearing but not deeply Feulgen positive.
Feb 17 9.00 A.M.	Sputum more viscid but not to control levels vital capacity 1250 ml.	Fibrils longer but not aligned in strands little ground substance.

Case 2—A woman, aged 58, with two weeks history of severe malaise, weakness sweating cough with little sputum, and pain in the left side of the chest.

Date	Clinical data and therapy	Cytochemical findings in pleural exudate
Jan 20	Admitted flushed and exhausted with dullness at left base. radiography showed diffuse shadow in same area. Penicillin I.M. 500 000 units daily until Jan 24. Aureo mycin Jan. 24-28.	—
Jan. 30	Chest aspiration 60 ml of thick tenacious greenish pus giving lactose fermenting coliform bacillus in culture. Penicillin 500 000 units injected intrapleurally.	Fine thin strands of Feulgen positive material between deeply stained nuclei of enmeshed cells.
Jan 31	Chest aspiration 165 ml of thick ropey greenish exudate difficult to aspirate. D _N ase 0.25 mg in 10 ml of saline solution injected intrapleurally with penicillin 1 000 000 units.	Appearances similar to above but Feulgen-negative ground substance slightly increased.
Feb 1	Chest aspiration 140 ml of moderately thick smooth pus running more readily through the needle.	Pus-cell nuclei still stain. Feulgen positively fibrils thicker more diffuse and many fragmented.
Feb 2	Chest aspiration 120 ml of free flowing greenish exudate giving profuse growth of <i>Bact. coli</i> on culture. D _N ase 0.25 mg in 10 ml of saline solution and penicillin 1 000 000 units injected intrapleurally.	Fibrils infrequent thin, and discreet ground substance much more diffuse and cells relatively more numerous.

Fig 1—Photomicrographs of sputum wet fixed in Susa solution and Feulgen-stained (a) purulent sputum showing Feulgen-positive fibrils arranged in strands and entangling leucocytes (b) non-purulent mucinous sputum showing Feulgen reaction confined to nuclei of leucocytes which are embedded in muco protein ($\times 100$)

ion is an obligatory activator, and the gelatin protects the unstable enzyme in solution. The fresh solution was sterilised by Seitz filtering, dispensed in 5 ml bottles, and stored at 5°C. Full bacteriological tests for sterility were made through the kindness of Dr W Hayes and Dr G I M Ross.

Cytochemical Tests

For investigating the action of the enzyme we have used a technique previously found reliable in the study of cellular nucleoproteins (White 1947, 1950). DNase activity was very high, and proteolytic activity not appreciable at enzyme concentrations up to 0.2 mg per ml, though slight proteolysis occurred at higher concentrations. No appreciable fibrinolytic activity was shown at a final concentration of 0.5 mg per ml, only slight softening of the fibrin clot, without any liquefaction, occurred after eighteen hours at 37°C.

The sputum samples were smeared on to glass slides and fixed while wet in Susa solution for an hour. Wet preparations of blood cells or other test preparations were fixed in the same way. In the *in vitro* experiments the slides were covered with test enzyme solution or control solution minus enzyme, and kept at room temperature, or at 37°C, for an hour or more. Next they were washed and stained by the pyronin methyl green or Feulgen methods. The latter is generally considered a highly specific cytochemical test for DNA (Feulgen and Rossenbeck 1924), and the former method gives a useful and reliable distinction between the two forms of nucleic acid (Brachet 1942).

In the Feulgen preparations of purulent sputa long fibrils of Feulgen positive material are to be seen running between the leucocytes and enmeshing them. In comparative studies changes in the number and structure of these fibrils are readily appreciated on high power microscopy.

Viscosity Measurements

It is evident that the presence of fibrils confers a structural

rigidity rather than a true solution viscosity on the sputum, rendering straightforward viscometry very difficult.

Comparative measurements of the viscosity of the sputum samples were estimated on a modification of the ball viscometer described by Lucas and Henderson (1936), using 9.5 cm of a tube of bore 6 mm, and a ball bearing of 3 mm diameter (weight 2.0 g) or 0.25 ml of mercury (weight 3.4 g). As Lucas and Henderson found with saliva, the viscosity of sputum decreases with time after collection, rapidly at body temperature but appreciably at 5°C. The decrease is presumably due to enzyme activity within the sample, and this made serial studies on fresh material from patients practically impossible. One spasm of coughing seldom produced sufficient for making

estimations with the equipment described. But controlled *in vitro* studies or mixed samples of relatively fresh sputum enabled significant differences to be detected.

Inhalation Spray

The DNase was made up in various strengths—0.05 mg and 0.5 mg per ml—in $M/50$ $MgCl_2$ with 1% gelatin, Seitz filtered, and stored in 5 ml quantities at 5°C till used. The lowest concentration was found too low for consistent clinical results, though a cytochemical effect was obtained. The efficacy of the spray was demonstrated beforehand on fixed smears of cells. The higher concentrations proved more satisfactory clinically. The spraying apparatus was the commercially available 'Deedon,' modified to give a flow of vapour, through a 3 in glass tube of about 1 in diameter, directly into the mouth. A flow of 6–8 litres a minute of 5% carbon dioxide and 95% oxygen was supplied through a T tube. The other wing of the T was closed by the patient's thumb during inspiration and open during expiration, in the manner described by Barach (1945). In the

Fig 2—Photomicrographs showing effect *in vitro* of deoxyribonuclease on Feulgen reaction of purulent sputum (a) control sample after two hours' incubation at 37°C showing many Feulgen positive fibrils and leucocytes; (b) sample of same sputum after action of deoxyribonuclease showing disappearance of Feulgen-positive fibrils but persistence of intact cell nuclei ($\times 400$)

according to age, are set out in table I, which shows that organic pathological conditions of the endometrium were found in 139 cases.

Though most workers restrict the use of the term "functional uterine hemorrhage" to cases of abnormal bleeding in the absence of any palpable lesion of the reproductive organs, it is occasionally used in a different sense. Bédère (1934, 1938a, b, and c) and Huffman (1942) speak of functional bleeding due to genital infection. Brewer and Jones (1948) say that hemorrhage can occur irrespective of the presence or absence of gross pelvic disease, and that the ovarian and endometrial changes are the same in either case.

PRESENT SERIES

To investigate further the above mentioned statement of Brewer and Jones (1948) in so far as the endometrial histology is concerned, an analysis was made of the clinical and histological findings in 1000 cases of abnormal uterine bleeding in the presence of palpable disease of the pelvic organs which might explain it. These patients were treated in the Royal Samaritan Hospital for Women between Oct. 1, 1937, and April 19, 1949. It was impossible to obtain an absolutely consecutive series of cases, because in a few instances the clinical records were incomplete or missing. The information available was insufficient to enable an assessment to be made of the part played by such general conditions as blood dyscrasia in causing the bleeding in these patients. The following cases were specifically excluded from the series: all types of abortion, all cases in which the only pelvic abnormality present was slight symmetrical uterine enlargement or slight cystic enlargement of one ovary, and all cases of bleeding after the menopause.

Organic pelvic lesions were present in every case, the diagnosis being confirmed histologically in most of them. The details were as follows:

Lesion	No of cases
Uterine fibroids irrespective of size and position	530
Chronic salpingitis or salpingo-oophoritis	141
Adenomyosis of uterus	25
Chronic parametritis mainly of slight degree	27
Endometrioma of one or both ovaries	26
Ovarian neoplasms of various types	19

HISTOLOGICAL MATERIAL

The material available for histological examination consisted of the uterus in 628 cases, and of curettings in the remaining 372. No attempt was made in any instance to obtain endometrium at any particular time in the menstrual cycle, the patients being admitted to the hospital from the waiting list in the usual way and undergoing operation as soon as possible after admission. Though more information might have been obtained if it had been possible to choose the time of securing specimens, it will be shown that even in such a series, routine histological examination of the endometrium is desirable, irrespective of age.

HISTOLOGICAL FINDINGS

The details of the endometrial histology, arranged according to age, are shown in table II. For purposes of comparison each category in tables I and II will be discussed in turn, the cases in table I being referred to as the "functional" group and the cases in table II as the "organic". In comparing these series it should be noted that table I deals with an age group more than fifteen years younger than that in table II, and it is likely that this factor plays some part in the differences between the two. It would also have been interesting to have a control series of the endometrial findings in healthy women without abnormal uterine bleeding, but this proved impracticable.

Chronic Endometritis

In the "organic" cases chronic endometritis was found 40 times (4%), compared with 110 cases (11%)

TABLE I—ENDOMETRIAL HISTOLOGY IN 1000 CASES OF ABNORMAL UTERINE BLEEDING IN THE ABSENCE OF GROSS PELVIC DISEASE

Age (years)	No of cases	Chronic endometritis	Uterine polyp	Tuberculous	Malignant disease	Hyperplasia	Atrophy	Irregular shedding	Irregular ripening	No apparent abnormality
20 or less	36	2	0	1	0	9	0	0	0	24
21-30	242	40	3	5	0	22	0	1	6	163
31-40	243	41	1	1	5	32	3	3	10	197
41-50	362	27	2	5	5	145	5	9	10	156
Over 50	17	0	1	0	1	7	5	0	0	5
Total	1000	110	11	10	8	265	10	13	26	547

in the "functional" series. The endometritis was invariably interstitial and was diagnosed only when the endometrial stroma showed appreciable infiltration with lymphocytes and plasma cells. Of the 40 patients 15 gave no history of pregnancy. The following histological pictures were seen:

	No of cases
Endometrium in proliferative phase of cycle	23
Endometrium in secretory phase of cycle	6
Endometrial hyperplasia	7
Irregular ripening of endometrium	5
Endometrial atrophy	1

The relatively high incidence of chronic endometritis in the "functional" cases is of interest. In view of the fact that chronic salpingitis or salpingo-oophoritis occurred in 141 of the "organic" cases and chronic parametritis in 27, one might reasonably expect a high incidence of endometritis in these conditions. In the 40 cases under review chronic adnexal infection occurred 17 times and chronic parametritis once.

Uterine Polyp

Uterine polyp was discovered in 18 cases in the "organic" group (1.8%). In 16 instances the polyp was of the mucous endometrial type and in the remaining cases fibroid polyp was found. Uterine fibroids were present in all 18 cases. This figure of 1.8% does not differ significantly from that of 1.1% found in the "functional" series.

Endometrial Tuberculosis

In a previous communication (Sutherland 1943) unsuspected tuberculosis of the endometrium is discussed in detail and the published reports on tuberculosis of the uterus are reviewed. Of 58 cases of uterine tuberculosis 34 were apparently limited to the uterine body and showed no evidence of involvement of other pelvic structures on clinical examination. In 9 of these 34 cases the principal complaint was profuse and sometimes irregular bleeding. The occurrence of endometrial tuberculosis on 9 occasions in the "organic" series (0.9%) is essentially similar to that found in the "functional" group (1.0%). Of the 9 patients 8 were nulliparous, and the 9th had had a miscarriage. Adnexal thickening was noted in 6 of the 9 cases.

TABLE II—ENDOMETRIAL HISTOLOGY IN 1000 CASES OF ABNORMAL UTERINE BLEEDING IN THE PRESENCE OF GROSS PELVIC DISEASE

Age (years)	No of cases	Chronic endometritis	Uterine polyp	Tuberculous	Malignant disease	Hyperplasia	Atrophy	Irregular shedding	Irregular ripening	No apparent abnormality
20 or less	-	0	0	2	0	1	0	0	0	2
21-30	75	11	0	1	0	0	0	0	0	55
31-40	306	14	6	4	5	25	15	0	0	253
41-50	529	11	9	15	15	125	23	0	0	350
Over 50	53	2	3	0	6	27	23	0	0	33
Total	1000	40	18	9	23	195	49	0	15	648

Feb 4	Chest aspiration 170 ml of watery green fluid Penicillin 1,000,000 units injected intrapleurally	Cells still in strands, but fibrils granular thick and diffuse
Feb 6	Chest aspiration 150 ml of watery green fluid	Strands very diffuse, no fibrils, cells degenerating
Feb 7	Chest aspiration 30 ml of watery green fluid	A few fibrils less ground substance numerous cells more
Feb 10	Operation rib resected and fluid purulent exudate removed visceral pleura unusually thin	

Subsequent clinical studies were made on two young bronchiectatic patients, the enzyme being used in a concentration of 0.5 mg per ml and a dosage of 10 ml a day (5.0 mg of D N ase a day) divided into three doses. In one case given full dosage from the start there was subjective improvement, the patient said he could walk up two flights of stairs, without stopping, for the first time in the last three years of his thirteen years of bronchiectasis. He also stated that he slept better, breathed more easily on awakening, and brought up his sputum more readily, and that his chest felt lighter. This improvement took place coincidentally with the administration of the enzyme, whereas 100,000 units of penicillin had been given by the same route daily for nine days without producing any improvement and had been stopped five days before the exhibition of the enzyme. The quantity of sputum expectorated increased the day after the first enzyme inhalation, and then decreased. Cytochemical changes were evident the day after the first inhalation and are shown in fig 3. They were still present during the subsequent week, though gradual return of thick strands was evident by the sixth day after the last inhalation. Similar cytochemical changes were observed in the second bronchiectatic patient, who was started on the lower dosage and showed less clinical effect.

Endotracheal injection by the oral catheter technique (as used for lipiodol) was done on two occasions, with the cooperation of Dr D G James, but without demonstrable beneficial effect.

None of the patients to whom D N ase was given by any of several routes showed symptoms of toxicity, and no febrile reactions occurred. The bacterial flora cultured from the purulent sputa were all organisms commonly inhabiting the upper respiratory tract, with predominance of *Strep viridans*, in one case only was a group A haemolytic streptococcus found.

DISCUSSION

The findings of Sherry et al (1948, 1949) and Tillett et al (1948, 1949, 1950) on the importance of D N P in viscid purulent materials, and the action of D N ase on these, are substantiated. A few *in vivo* studies suggest a rapid action and a long lasting effect of ox pancreas D N ase on purulent material within the human chest. The administration of the enzyme by inhalation spray may prove a useful adjunct to antibiotic therapy of acute and particularly of chronic bronchial inflammatory diseases that are so prevalent in this country. D N ase might prove also to be of some value in other purulent conditions, such as chronic sinusitis, otitis media, cystitis, and so forth, though we have not explored these possibilities.

The enzyme, which is specific in attacking only D N A, seems to be antigenic in the rabbit, but no sensitivity reactions were observed in patients in whom there were intervals of from four days to a month between courses of inhalation of the D N ase. This enzyme has no effect on true mucinous sputum, such as commonly arises in asthmatic patients. The preparation had no more than a trace of residual proteolytic or fibrinolytic activity.

SUMMARY

Some of the cytochemical characteristics of viscid, purulent sputum are described, deoxyribonucleoprotein fibrils being an important constituent.

Treatment of such sputum with deoxyribonuclease an enzyme isolated from ox pancreas, reduced the number of these fibrils and made the sputum less viscous.

A method of spray inhalation of this enzyme is described for patients with chronic chest infection. Clinical benefit was obtained with repeated inhalations containing 5 mg of deoxyribonuclease a day.

No toxic or anaphylactic reaction was encountered in the clinical studies.

We are indebted to Prof J McMichael, Dr J G Scadding, and other colleagues for permission to study their patients, Prof J H Dible and Prof J N Davidson for advice and criticism, Mr L H Turnbull for technical help with the Feulgen staining, and Mr K G Moreman, A.B.F.S., for the photomicrographs.

HISTOLOGY OF THE ENDOMETRIUM IN "ORGANIC UTERINE HÆMORRHAGE"

ARTHUR M SUTHERLAND,

M D Glasg, FR FCS, MR COG

ASSISTANT SURGEON, ROYAL SAMARITAN HOSPITAL FOR WOMEN, GLASGOW

In recent years there have been many publications on functional uterine hæmorrhage, or dysfunctional uterine hæmorrhage, as it is sometimes called. These terms are usually applied to cases of abnormal uterine bleeding which is not explained by any palpable lesion of the reproductive organs. Smith (1944) regards the use of the word "functional" as an admission of ignorance of the true cause of the bleeding.

I have already reviewed the recent literature of this subject (Sutherland 1949b) and have considered in some detail the histology of the endometrium in functional bleeding (Sutherland 1949a). I analysed the histological findings in the endometrium in 1000 cases of abnormal uterine bleeding in the absence of gross pelvic disease, all types of abortion and all patients with bleeding after the menopause being excluded. The results, arranged

SUMMARY

An analysis was made of the histological findings in the endometrium in 1000 cases of abnormal uterine bleeding in the presence of gross pelvic disease which might explain it. All patients with postmenopausal bleeding and all types of abortion were excluded.

In 90 cases organic pathological lesions of the endometrium were found. Chronic endometritis occurred in 40 cases, uterine polypi in 18, tuberculosis in 9 malignant disease in 23. In the remaining 910 cases no organic pathological conditions of the endometrium were found. Endometrial hyperplasia occurred 195 times, endometrial atrophy 49 times, and irregular opening of the endometrium 18 times. The remaining 6·8 specimens appeared normal.

These findings, considered in conjunction with those of a previous series of 1000 cases in which there was abnormal uterine bleeding but no gross pelvic disease, demonstrate the necessity for routine histological examination of the endometrium in all cases of abnormal uterine bleeding, whatever the patient's age.

I wish to thank Prof. T. Ferguson for his helpful criticism and advice regarding the statistical aspect of this paper, and Drs. D. McIntyre, J. Hewitt, and W. Clement for permission to study case records from their files.

Preliminary Communication

BACTERIAL POLYSACCHARIDES IN THE DIAGNOSIS OF INFECTIONS

THE POLYSACCHARIDE LYSIS TEST

A new field in laboratory technique has been opened by the demonstration of Middlebrook and Dubos (1948) that adsorption of a heat-stable polysaccharide fraction of *Mycobacterium tuberculosis* H37Rv on sheep erythrocytes renders them specifically agglutinable by sera from immunised animals or from patients with active tuberculosis. Scott and Smith (1950) showed that equivalent results could be obtained with Old Tuberculin as the sensitising agent but the use of a haemagglutinating system inevitably leads to anomalous results from the occasional presence of heterophil antibodies. Keogh et al. (1948) and Fisher and Keogh (1950) showed that the addition of complement to the reacting system caused specific haemolysis. This reaction, which we call the polysaccharide lysis test (P.L.T.) seemed to us to be applicable to various infections and we have prepared satisfactory active fractions from the salmonellae (modifying the Widal reaction) from *Proteus* (modifying the Weil-Felix reaction), *Neisseria gonorrhoea* (super-sensitising the gonococcal complement fixation test) and *Mycobacterium tuberculosis*. The use of *S. typhi* O polysaccharide in the diagnosis of typhoid fever is described elsewhere by Thomas and Menne (1950), and the use of *Proteus* A K OXK polysaccharide in the diagnosis of scrub-typhus has been described by O'Connor and MacDonald (1950). We are here briefly reporting our results to date with particular reference to tuberculosis and gonorrhoea; full details will be published elsewhere.

METHODS

The selection of sheep cells for the reacting system is arbitrary and conditioned by their availability and ease of storage in 5% sodium citrate (Evans 1950). Preliminary absorption of the test serum (30 minutes at room-temperature) is necessary to remove heterophil antibodies but this has not proved an obstacle in practice. Theoretically, Forssman deficient rabbit cells are the ideal. Experiments with *S. typhi* polysaccharide showed no differences in titre between sensitised human group O cde/cde sheep rabbit, chicken, or guinea-pig erythrocytes.

Inactivated sera after absorption with untreated sheep cells are set up in serial doubling dilutions of 0.25 ml unit volume in 3 $\frac{1}{2}$ in. tubes. To each is added 1 vol. of sensitised cell suspension and 2 vol. of complement containing 1 Kolmer unit. Appropriate controls (serum + untreated cells, sensitised cells + complement sensitised cells — saline, known positive and negative sera in full) are set up and the whole incubated for 1 hr at 37°C. The end point is taken as the highest dilution showing sparkling haemolysis (titres given are reciprocals of the original and not the true final serum dilution).

Sensitised cells are prepared by treating packed washed sheep cells with 10 vol. of 0.1% polysaccharide in saline solution for 2 hr at 37°C washing three times with saline and resuspending to 0.5% concentration in saline solution. With the defined reacting system no differences were noted between 0.5, 1 and 2% suspensions: the first was selected as conserving polysaccharide. Sensitised cells seem to be more stable than untreated cells: suspensions remaining potent and unhaemolysed for a week or more at 20°C. The 0.1% polysaccharide concentration is arbitrary, but that of *N. gonorrhoea* requires to be of this order, *S. typhi* O polysaccharide is active in dilutions of 1:10³. Cells sensitised with gonococcal polysaccharide show a relatively rapid loss of sensitivity and when tested against the same serum, may show a fourfold to eightfold reduction of titre in 3 or 4 days. Per contra this may be due to instability of the natural antibody and the point, being of practical importance, required further investigation.

We have prepared serologically active polysaccharide fractions by the following methods:

i. Papd freezing (dry ice-alcohol) and thawing (56°C) twenty times.

ii. Papan digestion for 6 hr at 52°C at pH 6 of fresh suspensions from solid media or of acetone-dried bacterial bodies (Freeman et al. 1949) followed by neutralisation with N/10 NaOH.

iii. Treatment of similar suspensions with the lytic product of *Streptomyces albus* (Maxted 1948).

These methods yield a polysaccharide-containing supernatant fluid which may be used directly for sensitisation.

iv. Precipitation of the F68 polysaccharide by 65% v/v ethanol from ice-co'd trichloro-acetic acid extracts of acetone dried bacterial bodies (Boivin et al. 1933), the product is purified by dialysis and dried in vacuo from acetone.

v. Ethanol precipitation from an alkaline filtrate (N/4 NaOH) of large volume (10 litres) 10-day over-cultures (Ashenburg et al. 1950). The crude precipitate is purified from solution in 0.1M sodium acetate-acetic acid buffer (pH 4.5) by repeated extractions with a chloroform-butanol mixture reprecipitated with 1.5 vol. of ethanol and dried in vacuo from acetone.

Both these methods yield a pure dry polysaccharide which can be used quantitatively. Method v gave maximal yields and seems to be that of choice for large-scale production.

vi. Alkaline hydrolysis (N/4 NaOH) for 6 hr at 56°C of a heavy suspension or dense fluid culture and precipitation with 65% v/v ethanol. The polysaccharide is allowed to precipitate overnight at 2°C collected by centrifugation, and either acetone-dried for storage or used directly.

A single experiment of note was the preparation of the pure FX flagellar antigen d of *S. typhi* from the cells of a

Malignant Disease of Uterus

There were 23 cases of malignant disease of the uterus in the "organic" series (2.3%) as compared with 8 examples in the "functional" group (0.8%). Possibly the rather higher incidence in the "organic" series is due, in part at least, to the larger numbers of patients in the later age groups in that series. As would be expected, all 23 patients were in the higher age groups, the youngest being aged thirty-two. Carcinoma of the uterine body occurred in 19 cases, including the patient aged thirty-two, and sarcoma was found in the remainder. Uterine fibroids were present in all 23 cases, and 1, in addition, had bilateral ovarian carcinoma. These figures indicate the desirability of histological examination of the endometrium in all cases of fibroids with abnormal uterine bleeding, of 830 patients with fibroids in the present series 23 had malignant disease of the endometrium (2.8%). According to Novak (1947) the presence of fibroids may possibly predispose to the development of adenocarcinoma of the uterine body. Kelly and Cullen (1909) found 25 examples of adenocarcinoma in "over 1400 cases of myomatous uteri." McDonald (cited by Novak 1947) found 20 cases of adenocarcinoma in 700 cases of myoma, and similar figures are reported by Stewart (cited by Novak 1947). These findings are in reasonable agreement with those in the present group of cases.

Endometrial Hyperplasia

The extensive literature on cystic glandular hyperplasia of the endometrium has already been reviewed (Sutherland 1949a), and it has been pointed out that great differences of opinion exist about the incidence of this condition, and that these differences may, to some extent, be due to different conceptions of what constitutes endometrial hyperplasia. In the present cases endometrial hyperplasia was found on 195 occasions (19.5%), as compared with 265 in the "functional" series (26.5%). Among these 195 cases uterine fibroids were found in 108, chronic pelvic infection in 19, adenomyoma of uterus in 10, endometrioma of ovary in 3, and ovarian neoplasm in 3.

Endometrial Atrophy

A study of the literature of endometrial atrophy in relation to functional uterine bleeding (Sutherland 1949a) shows that opinions differ widely on this condition. In the present cases the term is applied only where the endometrium was thin and scanty, with infrequent inactive glands, or where the amount of tissue was so small as to make accurate description impossible. The incidence of atrophy in the "organic" cases was 4.9%, as compared with 1% in the "functional" group. In these 49 cases uterine fibroids were present in 44 instances, adnexal infection in 4, ovarian neoplasm in 2, adenomyoma of uterus in 1, and endometrioma of ovary in 1. Most of these cases occurred in the later age groups. The appreciably higher incidence of atrophy in the "organic" group may be due to the association with uterine fibroids in most cases.

Irregular Shedding of Endometrium

The literature of this condition is discussed in an earlier communication (Sutherland 1949a). According to Holmstrom and McLennan (1947) the phrase "irregular shedding of the endometrium" is used to indicate a specific type of functional uterine bleeding which is characterised by prolongation of cyclic menstrual bleeding from progestational endometrium and often, in addition, by an increase in the amount of bleeding. The diagnosis is suggested by the typical clinical history of regularly recurring menorrhagia and is substantiated if secretory endometrium is obtained by curettage during the long continued bleeding, well beyond the time when endometrial regeneration would normally have occurred.

They state that, for diagnosis, the patient must be curetted on the fifth or sixth day of the menstrual period, since endometrium obtained on the first day of the period in a normal woman will show many of the characteristics of irregular shedding.

In the "functional cases" irregular shedding was found on 13 occasions (1.3%). Probably, however, the true incidence of irregular shedding in such cases is appreciably higher, since relatively few of these patients were curetted during a spell of bleeding. The figures from the literature (Sutherland 1949a) support this suggestion. In the "organic" cases no examples of irregular shedding were found, but it is impossible to draw any conclusions about the incidence of this condition in view of the fact that these patients were very rarely operated on during the bleeding.

Irregular Ripening of Endometrium

This condition has a relatively scanty literature (Sutherland 1949a). It represents a mixture of the proliferative and secretory phases of the menstrual cycle. On histological examination the peripheral zone of the endometrium shows considerable areas which are definitely non secretory and others which are definitely secretory in appearance. In some cases the non secretory elements predominate, and in others the distribution is more patchy. To make such a diagnosis histologically, these changes must be observed in the functional layer of the endometrium, and a considerable number of glands must be involved.

In the "organic" cases irregular ripening was found on 18 occasions (1.8%). This figure is in reasonable agreement with that of 2.6% in the "functional" series. In these 18 cases fibroids were present in 13, chronic pelvic infection in 5, and adenomyoma in 1. Possibly a higher figure might have been obtained if routine examination of the endometrium in the premenstrual phase of the cycle had been carried out.

Normal Endometrium

The endometrium did not show any histological abnormality in 648 of the "organic" group (64.8%), as compared with 547 in the "functional" cases (54.7%). Secretory changes were seen in 253 of the "organic" series and 263 of the "functional" group. The remaining specimens in each category were in the proliferative phase of the cycle. Probably a higher incidence of secretory endometria would have been found in either group if it had been feasible to obtain endometrium towards the end of the cycle in every case. From the information available it is impossible to estimate the number of patients with anovulatory bleeding in these groups.

CONCLUSIONS FROM HISTOLOGICAL FINDINGS

Evidence has been put forward to show that it is desirable to examine the endometrium histologically in all cases of abnormal uterine bleeding even if there is some pelvic disease which might explain the bleeding. By doing so unsuspected organic conditions of the endometrium can be discovered. The histological findings described here show that the endometrial patterns in "organic uterine bleeding" are essentially similar to those in "functional" cases, the only striking difference being in the incidence of chronic endometritis. It is impossible to say how often the associated gross pelvic disease is responsible for the abnormal bleeding in such cases. Though the bleeding often ceases after the presumed causal condition has been removed, many patients with fibroids, salpingo oophoritis, and other gross pelvic lesions have normal menstrual cycles. The figures given here suggest that too much emphasis may previously have been laid on the importance of the endometrial histological appearance in functional uterine haemorrhage.

SUMMARY

An analysis was made of the histological findings in the endometrium in 1000 cases of abnormal uterine bleeding in the presence of gross pelvic disease which might explain it. All patients with postmenopausal bleeding and all types of abortion were excluded.

In 90 cases organic pathological lesions of the endometrium were found. Chronic endometritis occurred in 40 cases, uterine polypi in 18, tuberculosis in 9 malignant disease in 23. In the remaining 910 cases no organic pathological conditions of the endometrium were found. Endometrial hyperplasia occurred 185 times, endometrial atrophy 49 times, and irregular opening of the endometrium 18 times. The remaining 648 specimens appeared normal.

These findings, considered in conjunction with those of a previous series of 1000 cases in which there was abnormal uterine bleeding but no gross pelvic disease, demonstrate the necessity for routine histological examination of the endometrium in all cases of abnormal uterine bleeding, whatever the patient's age.

I wish to thank Prof T. Ferguson for his helpful criticism and advice regarding the statistical aspect of this paper, and Drs. D. McIntyre, J. Hewitt, and W. Clement for permission to study case records from their files.

Preliminary Communication

BACTERIAL POLYSACCHARIDES IN THE
DIAGNOSIS OF INFECTIONS
THE POLYSACCHARIDE LYSIS TEST

A new field in laboratory technique has been opened by the demonstration of Middlebrook and Dubos (1948) that adsorption of a heat stable polysaccharide fraction of *Mycobacterium tuberculosis* H37Rv on sheep erythrocytes renders them specifically agglutinable by sera from immunised animals or from patients with active tuberculosis. Scott and Smith (1950) showed that equivalent results could be obtained with Old Tuberculin as the sensitising agent, but the use of a haemagglutinating system inevitably leads to anomalous results from the occasional presence of heterophil antibodies. Keogh et al. (1948) and Fisher and Keogh (1950) showed that the addition of complement to the reacting system caused specific hemolysis. This reaction, which we call the polysaccharide lysis test (P.L.T.), seemed to us to be applicable to various infections, and we have prepared satisfactory active fractions from the salmonellae (modifying the Widal reaction), from *Proteus* (modifying the Weil-Felix reaction), *Neisseria gonorrhoeae* (superseeding the gonococcal complement fixation test), and *Mycobacterium tuberculosis*. The use of *S. typhi* O polysaccharide in the diagnosis of typhoid fever is described elsewhere by Thomas and Mennie (1950), and the use of *Proteus* A K OOK polysaccharide in the diagnosis of scrub typhus has been described by O'Connor and MacDonald (1950). We are here briefly reporting our results to date, with particular reference to tuberculosis and gonorrhoea, full details will be published elsewhere.

METHODS

The selection of sheep cells for the reacting system is arbitrary and conditioned by their availability and ease of storage in 5% sodium citrate (Evans 1950). Preliminary absorption of the test serum (30 minutes at room temperature) is necessary to remove heterophil antibodies, but this has not proved an obstacle in practice. Theoretically, Forssman deficient rabbit cells are the ideal. Experiments with *S. typhi* polysaccharide showed no differences in titre between sensitised human group O cde/cde, sheep, rabbit, chicken, or guinea pig erythrocytes.
